"1. On first waking in the morning, and also on going to bed at night, sip slowly from a quarter to half a pint of water, cold or hot. 2. On rising, take a cold or tepid sponge-bath, followed by a brisk general towelling. 3. Clothe warmly and loosely; see that there is no constriction about the waist. 4. Take three simple but liberal meals daily; and, if desired, and it do not disagree, take also a slice of bread-and-butter and a cup of tea in the afternoon. When tea is used it should not be hot or strong, or infused over five minutes. Avoid pickles, spices, curries, salted or otherwise preserved provisions, pies, pastry, cheese, jams, dried fruits, nuts, all coarse, hard, and indigestible foods taken with a view of moving the bowels, strong tea, and much hot liquid of any kind, with meals. 5. Walk at least half an hour twice daily. 6. Avoid sitting and working long in such a position as will compress or constrict the bowels. 7. Solicit the action of the bowels every day after breakfast, and be patient in soliciting. If you fail in procuring relief one day, wait until the following day, when you will renew the solicitation at the appointed time. And if you fail the second day, you may, continuing the daily solicitation, wait until the fourth day, when assistance should be taken. The simplest and best will be a small enema of equal parts of olive-oil and water. The action of this injection will be greatly helped by taking it with the hips raised, and by previously anointing the anus and the lower part of the rectum with vaseline or with oil. 8. If by the use of all these means you fail in establishing the habit of daily or of alternate daily action of the bowels, it may be necessary to take artificial help. And your object in doing this is not to produce a very copious dejection, or to provoke several smaller actions: your object is to coax or persuade the bowels to act after the manner of nature, by the production of a moderate more or less solid-formed discharge. Before having recourse to drugs, you may try, on waking in the morning, massage of the abdomen, practised from right to left along the course of the colon;

and you may take at the two greater meals of the day a dessert-spoonful or more of the best Lucca oil."

The author maintains that if this programme be faithfully adhered to, aperients will rarely be found necessary. Of course, Clarke admits that the use of drugs is not altogether avoidable. His own preference is for the compound aloin pill (aloin, gr. ½; ext. nucis vom., gr. ½; ferri sulph., gr. ½; myrrh and soap enough to make one pill), taken half an hour before the last meal of the day. We fully agree with Dr. Clarke in believing that "the particular agent employed for the relief of constipation is of much less importance than its mode of operation." Whatever the remedy, it should act after the manner of nature in securing a daily formed stool. If in place of yielding to the importunities of patients demanding new and stronger aperients physicians would always take the pains to insist upon some such plan as outlined above, we have no doubt that there would be less trouble for and from constipated persons.

QUACK MEDICAL ADVERTISEMENTS AND THE RELIGIOUS PRESS.

We have been very much edified by the article which, in response to one of our editorials on quack advertisements and the religious press, appeared in the columns of the *Christian Advocate* for February 24th. We heartily indorse the principles which govern the editor with reference to all advertisements. We accept as eminently proper the criticism which he makes on some of the advertisements that have appeared in The Medical Record. We also acknowledge the receipt of the suggestion that "it" (The Record) "could find a better field for its missionary labors by selecting some of those religious papers which admit the worst kind of quack remedies supported by ministerial certificates," etc. We do not, however, adopt the suggestion that we could find a better field. Why? Simply because the columns of the *Advocate* have been so nearly clean that it is worth a double effort to make them *entirely* so. Of course, the *Advocate* does not wish to avail itself of the argument that because other religious papers soil themselves altogether it may be excused for being a little bit impure. We are happy to say that we believe that the principles by which the *Advocate* is governed would not allow it to seek such a refuge, however much the editor's parting shot may have of that appearance.

But let us return to the principles which govern the editor with reference to advertisements.

The editor of the *Christian Advocate* "gives instructions to the superintendent of the advertising department; these instructions are: 1. Admit no advertisements which declare that the medicine advertised is an infallible cure. 2. Admit none that declare that they cure diseases."

This is an excellent instruction, and one which those religious newspapers that admit to their advertising columns "the worst kind of quack remedies supported by ministerial certificates" would do well to take cognizance of. Now with reference to the medicine in question. The criticism of the *Advocate* on the advertisement as it at this date stands in its columns is well deserved, and we hope that the superintendent of the advertising department will "require the advertisement to be trimmed down several times" more. "It does state," says the editor, "that in croup it gives almost instant relief." "Not a solitary direct statement of its *infallibility*, or even of its *curing* any disease, is found in the advertisement."

On this we have to offer the following: It does state that "it *never fails* to give almost instant relief." Never fails and infallibility are so nearly the same that we feel warranted in assuming that those who read advertisements because they are in search of remedies will be led to believe that this particular one *always* relieves and that *almost instantly*.

The whole secret of the success of quack advertisements lies in words which convey the idea of certainty—"best," "unsurpassed," "never fails," etc. We trust that the *Advocate* may see its way clear to still further apply the pruning-knife. We make the bold assertion that the remedy has not yet been discovered that "never fails to give almost instant relief in that frightful malady, croup." The proprietors of this remedy in giving such a statement to the public have taken a position never yet assumed successfully by any intelligent, educated physician, and, by so much at least, the *Advocate* should not aid in sustaining what may give rise to deception.

Besides, the editor of the *Advocate* would act very unwisely should he peril the life of one of his own children by assuming the responsibility of diagnosticating that "frightful malady," the croup. By the admission of no tices of remedies for such diseases, for in this instance *relief* may be only the luring precursor of death, the newspaper or the journal becomes accessory indirectly to an extent that holds it and its editor *responsible*. This is no new view to the editor of the *Advocate*, and we have read with pleasure his trenchant words against what was no greater danger than that which we have thus endeavored to point out.

From this standpoint we should say that no newspaper or medical journal should permit in its columns advertisements containing such language as the following: "The best known remedy for either," speaking of cough or cold in persons having a tendency to consumption. This is too grave a responsibility for anyone to assume, either professional or non-professional. Why? Simply because medical science has demonstrated at the bedside that there is no *best* remedy yet known. And yet the *Advocate* advertises it as "the best known remedy for either."

In the first advertisement under consideration the advertiser says that *coughs* are "more speedily, surely, and thoroughly stopped" "than by any other medicine," and that it "is unsurpassed for the relief of coughs."

Certainly, it requires no play upon words to make it appear that for coughs "the best known remedy," and that which *stops* coughs "more speedily, surely, and thoroughly than any other medicine," and "is unsurpassed for the relief of coughs," can, by any possibility, be truthfully applied to two remedies. And still the *Advocate* advertises both proprietary medicines.

The *Advocate* is evidently under conviction, and we doubt not that it will draw the lines even closer than it has yet done. Would that the medical profession and the medical journals had as honest and powerful an ally

in every religious newspaper in the land as they have in the *Christian Advocate*, for then the nostrum-venders might be driven from this field.

The statement that "it is impossible for the medical profession to take care of all the sick in the country" will not bear the test of either argument or criticism for a moment. That "thousands of persons live so far from physicians that they need some remedies in the house," doubtless is true; but it by no means follows that they cannot be supplied by the physicians of the country with remedies equally efficacious and much more trustworthy than those which are heralded in the advertising columns of the religious and secular newspapers.

We hope that the *Christian Advocate* will aid us with its clarion voice in preaching against the debasing practice of inserting quack medical advertisements in the columns of the religious press. We will also do the best that we can to keep our own garden free from weeds.

A SURGEON REMOVED BECAUSE HE PERFORMED LAPAROTOMY TOO OFTEN.

At the annual meeting of the Governors of the Liverpool Hospital for Women, the case of Dr. Imlach was made the subject of lively discussion, he having been accused of too frequent indulgence in spaying, and of varying from the consultation custom of the hospital. The controversy seems to have been based mainly on personal grounds, there being great jealousy and antagonism among the staff. On the question of re-electing the staff arising first, Dr. Briggs, a new member, was elected unanimously; secondly, Dr. Burton, who had been on the staff since the formation of the hospital, and who was pointedly accused by Mr. S. B. Bacon of being "the originator" of the quarrels, was elected by thirteen votes to nine; thirdly, when the case of Dr. Imlach's re-election came up, it was negatived by seventeen to sixteen votes.

The whole affair quite exceeds, in scandalousness and publicity, anything that we have ever been able to produce in this modest new world of ours. We salute our mother country. In the matter of exhibiting dirty professional linen, she has now got far ahead. As for Dr. Imlach, he has evidently been doing oöphorectomy well, but not too wisely.

EPIDEMICS OF PNEUMONIA IN THE COUNTRY.

In certain rare cases pneumonia attacks a community with a suddenness and to an extent which constitutes a veritable epidemic. In the *British Medical Journal* of August 11, 1883, Dr. Bruce describes the appearance of such an epidemic at Dingwall, a locality in which the disease had never prevailed before, except to a small extent. From May to September Dr. Bruce treated twenty-three cases, and Dr. John Adam twenty-four cases. Many of the patients lived far apart, and there was no evidence of contagion or of some specially limited local cause. The disease seemed to prevail just as influenza sometimes does, attacking persons indifferently.

Dr. Mackenzie, of the Isle of Skye, records the appearance of an epidemic of influenza in that locality, followed by the development of pneumonia in many of the persons attacked.

Dr. R. J. Foulis reports a very typical epidemic of pneumonia occurring in the vicinity of Wylam-on-Tyne. In a population of about two thousand, there appeared within two months one hundred and fifteen cases of pneumonia. The disease followed a very severe storm; it ran the usual course of croupous pneumonia; it attacked young persons mostly, and these of all classes. In fine, it had the appearance of an acute infectious disease.

The epidemics of pneumonia above described occurred in somewhat thinly settled districts, and are unlike the occasional epidemics of this disease seen in overcrowded garrisons or in sewer-gas-poisoned houses.

Doubtless some of our readers can recall epidemics of true croupous pneumonia occurring in rural localities. Careful observations of such phenomena would be of decided interest.

News of the Week.

Excision of the Larynx.—We learn from the daily papers that a larynx has been removed *in toto* by a Philadelphia surgeon. The patient died. The same operation with the same result has recently been done in Baltimore and London.

Dr. Lewis Fisher, formerly of Morristown, N. J., and later of this city, died recently at Jacksonville, Fla., in the forty-eighth year of his age.

A Death from Chloroform occurred in the practice of Dr. William H. Pancoast recently. The anæsthesia was not completely accomplished before death occurred. The man had a fatty heart.

The Tennessee State Medical Society meets at Nashville on the second Tuesday in April. It promises to be a specially large and interesting meeting.

Bacteriology and its Clinical Therapeutics is the tittle of the general address which will be delivered by Professor Mariani Semmola before the Ninth International Medical Congress.

The Sixteenth Congress of German Surgeons meets at Berlin on April 13th, 14th, 15th, and 16th next. Professor Richard von Volkmann will preside. One of the subjects of discussion will be, "Occlusion of the Intestines, Peritonitis, and Intestinal Perforation, from an Operative Stand-point," to be opened by Dr. Madelung, of Rostock.

The Sixth German Congress for Internal Medicine will be held at Wiesbaden, April 13th to 16th, under the presidency of Professor Leyden. Among the subjects announced for discussion are, "The Therapy of Phthisis," "Cerebral Localization," "Pathology and Therapy of Whooping-cough," "Pernicious Anæmia," "Tabes Dorsalis," and "Experimental Epilepsy."

The Death of Professor Béclard occurred quite suddenly on February 9th, in the sixty-ninth year of his age. He was Professor of Physiology in the Faculty of Paris, and made many important contributions to that science. His treatise on "Physiology" has long been a standard one in France, but never got much popularity outside that country. Béclard was Dean of the Paris Faculty.

Despatches Announce that Professor Virchow has won his seat in the Reichstag at the last elections.

The Alumni Association of Long Island College Hospital held its seventeenth annual banquet on the 2d inst.

The New York Polyclinic.—The Faculty of the New York Polyclinic tendered a reception to its numerous friends in its building, No. 214 East Thirty-fourth Street, on Wednesday, March 2d. One of the features of the occasion was the celebration of the matriculation of its thousandth student. The different clinic rooms were duly inspected, and the sociabilities terminated with an elegant supper.

An Enterprising Female Charlatan.—The *Pacific Record* states that a female doctor in San Diego, Cal., started a cancer epidemic, and her rooms were filled with patients, from each of whom she extracted a cancer "without pain," and was rapidly getting rich, until someone discovered that the "cancers" were pig-kidneys. Many female doctors have ridden this hobby of curing cancers into a good practice, without one atom of knowledge. It is only necessary to employ two or three women to declare that *they* have been cured, and the thing is done.

Jews in the Paris Faculty of Medicine.—Professors Germain Sée, Charcot, Hayem, Marc Sée, and some other prominent members of the Paris Faculty of Medicine are of Jewish descent.

Considerable Excitement has been caused in medical circles at Boston over the fact alleged by the *Boston Medical and Surgical Journal* that the following message was left on the slate of a Boston physician:

οἱ ἀναγκαῖοι ἐμὲ χρήζουσιν ὀίκαδε ἰέναι.

Several translations of this sentence have been offered, the best one being sent up by a surgeon of this city. When the facts are all brought out, it will probably be shown that the gentleman who left the message was a New Yorker, on a brief visit to the provinces.

The Pennsylvania Hospital has received the sum of $4,000, and the Woman's Hospital of Philadelphia $3,000, from the estate of the late Mr. John George.

Yorkville Medical Association.—The following officers have been elected for the ensuing year: President, Dr. C. J. McGuire; Vice-President, Dr. J. F. Monell; and Secretary, Dr. J. Blake White.

New York Post-graduate Medical School and Hospital.—Dr. Joseph O'Dwyer will give a course of instruction on intubation of the larynx on Wednesdays and Saturdays, at 3 P.M., at this institution.

A Doctor's Suicide.—Every house in Inverary, Scotland, belongs to the Duke of Argyle. Opposition to His Grace means banishment. Its government is delegated to a certain councillor, James Wyllie, who is the Duke's factor and chamberlain, and chairman of a co-operative store the greater portion of whose capital belongs to the Duke. The town council consists of the Duke's men. They are called the "concur" members, because they always say ditto to every motion of the factor, chamberlain, and storekeeper. Three years ago the medical officer reported the overcrowded state of the burgh. He was dismissed from his position as medical officer and his dwelling was taken from him. This persecution so weighed on him that he killed himself, and the house from which his wife and his children were ejected still remains unoccupied, as a warning, presumably, to all such meddlers. So says *Truth*.

Reviews and Notices of Books.

Practical Clinical Lessons on Syphilis and the Genito-urinary Diseases. By Fessenden N. Otis, M.D., Clinical Professor of Genito-urinary Diseases in the College of Physicians and Surgeons, New York, etc. New York, 1886.

This edition of Dr. Otis' work is merely a reprint of the publication issued in 1883 by Bermingham. It is now published by the author for the convenience of those who wish to make themselves familiar with his views and methods of practice. A true second edition, embodying the usual changes, eliminations, and additions made necessary by progressive science, is promised by the author at a later date.

Surgical Diseases of the Kidney. By Henry Morris, M.A., M.B., F.R.C.S., Surgeon to, and Lecturer on Surgery at, the Middlesex Hospital, London. 12mo, 555 pages, with six chromo-lithographic plates and forty engravings. Philadelphia: Lea Brothers & Co. 1886.

This work contains an account of those renal affections which are likely to interest the surgeon. Malformations, injuries, and all diseases that may bring up the question of an operation upon the kidneys are discussed by the author in a very satisfactory manner. The methods of nephrectomy, nephro-lithotomy, nephrotomy, nephrorraphy, and aspiratory puncture are described in detail.

Mental Diseases. By Charles F. Folsom, M.D. Pp. 204. 1886.

These pages were a contribution to the "American System of Medicine," and reprinted for the students in the Harvard Medical School. The writer has done fairly well in covering so wide a subject in so few pages, and the book will probably prove a valuable adjunct in instruction upon this branch of medicine, the importance of which, unfortunately, is too much overlooked in a medical course.

Diseases of Tropical Climates. Lectures delivered at the Army Medical School, by William Campbell Maclean, M.D. Pp. 337. London: Macmillan & Co. 1886.

These lectures are written in the most graphic and interesting manner. In a way they are models. They are full of illustration, practical hints, and instruction of how to meet those diseases which often prove more fatal in decimating the ranks of the British army than its enemies. He considers as diseases of tropical countries, Malaria; Intermittent, Remittent, Enteric, Relapsing, Dengue, and Yellow Fevers; Insolation, Diarrhœa, and Dysentery; Cholera, Diseases of the Liver, and Guinea-worm. He devotes a chapter to the disease called Beriberi, which prevails on the Malabar coast, in Ceylon, as well as in other parts of India. He describes it as an exceedingly fatal malady, characterized by anæmia in an extreme degree, numbness and motor paralysis of the lower extremities, scanty and high-colored urine, general œdema, with effusion into the serous cavities, chiefly the pleura and pericardium, occasionally acute pain, and oppression at the epigastrium, death occurring suddenly, either from dropsical effusion into the thoracic cavities, failure of the heart, or embolism.

On Disorders of Digestion, their Consequences and Treatment. By T. Lauder Brunton, M.D., D.Sc., F.R.S. 8vo, pp. 389. London: Macmillan & Co. 1886.

Diseases of the Stomach and Intestines.

A Manual of Clinical Therapeutics for the Student and Practitioner. By Professor Dujardin-Beaumetz. Translated from the fourth French edition by E. P. Hurd, M.D.; with illustrations and one chromolithograph. New York: William Wood & Co. 1886. Wood's Library of Standard Medical Authors.

Dr. Brunton's work is not a systematic treatise, as might perhaps be supposed, but consists of a collection of essays and lectures, written or delivered by the author at different times. The author almost too candidly states that if any one should attempt to read his book straight through, he would probably throw it aside in disgust, because he has in some cases repeated himself. We would not pass so harsh a judgment. Every chapter of the work is worth reading, showing, as it does, an alert and ingenious mind stored with knowledge and experience. The first three chapters of the book consist of the Lettsomian Lectures "On Disorders of Digestion, their Consequences and Treatment." Then follow miscellaneous essays. The first two are on headache, neuralgia, and other nervous diseases connected with the teeth; on the pathology and treatment of some forms of headache. The author here gives some very interesting points regarding the headaches of digestive origin, the nature of migraine, reflex headaches, etc. Subsequent chapters are devoted to dyspepsia, the uses, etc., of fat; the physiological action of alcohol on vomiting; the action of mercury on the liver; the action of purgative medicines; the action of tonics, of alteratives; indigestion as a cause of nervous depression, etc. All the topics treated of are "live" ones, and are treated of in an ingenious, interesting, and suggestive manner. We can recommend the book most heartily, as likely to prove of absorbing interest and of much practical value.

Dujardin-Beaumetz's work is one of quite a different character. It aims to be a treatise on gastro-intestinal disorders, studied from a therapeutical point of view. The author gives us some pathology, therefore, but mostly treatment. The work is written in the form of lectures, and has the disadvantage, consequently of being somewhat diffuse. The author writes clearly, however, and his description of modes of treatment are all the better for the copiousness of detail. The book is enriched with many notes, which the editor has judiciously placed at the end of the different chapters. These notes, taken in connection with the text, evince a great deal of erudition, and make of the book a veritable encyclopædia of information upon the subject of which it treats. The author calls attention to the recent investigations which French physicians have made upon the subject of dilatation of the stomach and the generation of putrid products in that organ. He believes that the further study of this subject is going to lead to a great change in our ideas of many of the morbid phenomena attendant on dyspepsia. We congratulate Dr. Hurd upon having been the means of presenting to the profession a work likely to be of such service, and upon the excellence of his translation.

Traité Élémentaire d'Anatomie Médicale du Système Nerveux. Par Ch. Féré. Paris: Aux Bureaux du *Progrès Médical*. 8vo, pp. 495. 1886. Elements of the Medical Anatomy of the Nervous System.

There is undoubtedly a widespread desire on the part of physicians to learn the latest views regarding the anatomy of the nervous system, and Dr. Féré has undertaken to present the subject in such a manner as to make it interesting and intelligible to the average reader. The introduction of the qualifying term "medical" means, we take it, that the author intends to give, as he goes along, enough of neuro-pathology to make his work practical.

Dr. Féré has the virtue, which most French authors possess, of writing clearly, and he has had an excellent training in neurology under Charcot. His book is, therefore, as might be expected, a work of more than average merit. We cannot, indeed, find fault with it, except that in his description of the finer portions of the nervous system, such as the different tracts in the medulla, pons, and cord, he is not quite complete, and he does not bring out by diagrams, etc., the fibre-system of the brain and cord as well as might be wished. The illustrations also are not of the best. Still, we can, on the whole, heartily commend the book to the general reader, and we trust his audience in America will be a large one.

Handbook of Practical Medicine. By Dr. Hermann Eichhorst, Professor of Special Pathology and Therapeutics at Zurich. Volume I. Diseases of the Circulatory and Respiratory Apparatus, one hundred and three wood engravings. Volume II. Diseases of the Digestive, Urinary, and Sexual Apparatus, one hundred and six wood engravings. Volume III. Diseases of the Nerves, Muscles, and Skin, one hundred and fifty-seven wood engravings. New York: William Wood & Co. 1886. Wood's Library of Standard Medical Authors.

Professor Eichhorst has long been favorably known to the medical public of this country for his contributions to general medicine and nervous pathology. His book has had a favorable reception abroad, and it fully sustains the reputation of the author. There are three things which characterize the work and give to it a particular value: these are the copiousness of the therapeutical discussions and suggestions, the extremely complete and almost encyclopædic thoroughness with which the author goes over the field of medical pathology, and finally, the admirable presentation of the subject of diseases of the nervous system, in which Professor Eichhorst has achieved some special fame.

The abundance of the illustrations, there being a total of three hundred and sixty-six, adds to the attractiveness and clearness of the work. We should be glad to have learned who was the translator of these volumes, for he has evidently done his work carefully and well.

The Genuine Works of Hippocrates, Translated from Greek, with a Preliminary Discourse and Annotations. By Francis Adams, LL.D., Surgeon. In two volumes. Vol. II. New York: William Wood & Co. 1886. Wood's Library of Standard Medical Authors.

There is little new that can be said now regarding the works of Hippocrates. The present volume is hardly of so much interest as the first, yet most of it can be read with interest, if not profit. The best thing in it, perhaps, is the chapter on "The Sacred Disease." In this Hippocrates shows how thoroughly his mind was freed from the medical superstitions of the day, and with what a philosophical mind he can discuss questions of medical pathology. As for his aphorisms, we have long thought them rather poor things, as most attempts at being aphoristical when dealing with things complex and inexact must necessarily be.

The Hippocratic oath is an immortal production, and deservedly so. "The Law" is a brief tract which, if written nowadays, would be considered rather commonplace. We have said that Hippocrates' "Surgery," as the first two-thirds of this volume might be called, is of lesser interest than his medical treatises. It is, nevertheless, a tolerably complete work so far as fractures and dislocations are concerned, and the editor, Dr. Adams, a surgeon himself, says that in this nineteenth century

no other author has treated the same subject so completely.

The illustrations at the end of the volume deserve notice, if only for their showing the characteristic physiognomy of the ancient Greek.

Rheumatism: Its Nature, Its Pathology, and Its Successful Treatment. By T. J. Maclagan, M.D. New York: William Wood & Co. 1886.

This work, which is one of the series of "Standard Medical Authors of Wood's Library," is an interesting and instructive consideration of rheumatism. The author regards the disease as miasmatic in origin as is malaria, and thinks that lactic acid is produced by the morbific action of parasitic organisms which have a predilection for fibrous and serous tissues, hence the reason of rheumatism affecting the joints and the pericardium. The author then proceeds to consider rheumatism of the vasculo-motor apparatus, and rheumatism of the locomotor apparatus. The efficiency of the salicyl compounds is due, he thinks, to the power which they have of combating the miasmatic organisms. Of all of these he prefers salicine. He says it is a bitter tonic, and has not the unfavorable action upon the stomach and heart of salicylic acid.

Manual of Dietetics. By J. Milner Fothergill, M.D., Edinburgh. New York: Wm. Wood & Co. 1886.

Dr. Fothergill's name has come to be associated with matters of diet, and his book will command attention as from one who has much experience in an important and an hithertofore neglected subject in connection with the health of humanity. Food, as the writer himself states, has had its pre-scientific stage, when the question was one of the palate, and not of the digestion. To-day the degenerate descendants of the eaters of venison pasty and roast boar must think whether peptic glands and gastric juices are equal to the task demanded of them. It was not exactly "*eye of newt and toe of frog*" that made the witch-like food of Charles V. of Germany. He, nevertheless, revelled in roasted horse, cats in jelly, lizard soup, and fried frogs, as delicacies of his menu. If Dr. Fothergill had been the court physician, with his present enlightenment, he would have discoursed learnedly to that gluttonous monarch, and told him of carbo-hydrates, albuminoids, fat-salts, and just what combination of vegetable, flesh, and fish were requisite to produce a proper condition in that monarch's alimentary apparatus, such as should most conduce to his well-being, and, consequently, to that of his subjects; and his scientific discourse would have turned the mind of the Emperor from thoughts of tickling his palate to the intellectual delight which a modern can enjoy, as, for example, that of watching the process of digestion in a test-tube. It is said that, in countries where certain diseases are prevalent, the plants or trees which furnish drugs corrective of the same abound; so in this century of prevalent dyspepsia, the consideration of food, in a dietetic and scientific aspect, becomes one of the features of the time, necessity having again performed the maternal duty and brought forth her offspring, invention. To turn from these somewhat rambling considerations of diet, past and present, to Dr. Fothergill's book, we find food dealt with in all its aspects and relations. Condiments, beverages, stimulants, fluid foods, preserved, canned, and prepared foods, and artificial digestive agents each claiming a chapter. In Part II. he treats of foods for infancy, youth, adult life, and old age, and for all the diseases which are encountered by the physician. Dr. Fothergill is sometimes florid in style, a little loose in diction, and not always as exact in detailing his theories and giving directions as so scientific a work would lead the reader to expect; but these are minor blemishes, which are easily forgiven in view of the value of most of the information given, and the thought-awakening power of the material placed at our disposal. It will certainly turn the attention of the physician too exclusively devoted to medication to the valuable auxiliary to be found in a diet suitably adjusted to the case in hand.

Manual of Operative Surgery. By W. Arbuthnot Lane, M.B., M.S., F.R.C.S., etc. 12mo. Pp., 276. London: George Bell & Sons. 1886.

The author of this manual is a demonstrator of anatomy, and the book itself smacks of the dissecting-room. Anatomical details are entered into with extreme minuteness, while the practical steps of the operations are almost entirely omitted. For example, in amputation at the middle of the thigh, it is much more important that the operator should draw down and cut short the tendons and nerves, than that he should know that he is cutting small branches of specified cutaneous nerves. The best sections are on ligations of vessels and excisions of bones and joints. Many recognized operations, such as litholapaxy, and Ogston's operation for flat foot, are not even mentioned. Nothing is said as to the importance of antiseptic details. An operative surgery without this is much less interesting than the play of "Hamlet" with *Hamlet* left out. To the general practitioner the book is of no use, while the practical surgeon will find it very unsatisfactory.

Reports of Societies.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, February 28, 1887.

Laurence Johnson, M.D., President, in the Chair.

Dr. P. A. Morrow read a paper on

THE DURATION OF THE SYPHILOGENIC CAPACITY IN RELATION TO MARRIAGE.

The fundamental characteristics of syphilis were two: First, prolonged virulence, and second, susceptibility to hereditary transmission. What is the duration of the contagious stage of syphilis? A century ago the majority of syphilographers would have answered that it began and ended with the chancre. At the present day it is impossible to fix a definite limit when the syphilitic organism is cleansed from the contagious element. The author of the paper then directed attention to the results of experimentation, and also to clinical evidence, which he regarded as conclusive that in the late tertiary stage the disease is still contagious. Especial attention was also directed to a paper published by Dr. F. N. Otis, in which the writer had taken a position that was opposed by an overwhelming mass of clinical testimony, that is, that after the termination of the second year it was impossible for a man, all manifestations of syphilis having disappeared, to communicate syphilis. Dr. Morrow believed that the doctrine of the paternal transmission of syphilis was supported by most authorities on general medicine, and also by most syphilographers.

He concluded that there was nothing constant in contagion, and nothing certain in heredity; that the modern division of syphilis into secondary and tertiary periods did not furnish a safe criterion concerning the contagious or the non-contagious character of the lesions; that the chronological completion of the secondary stage did not mark the definite disappearance of the virulent principle; that in the immense majority of cases the contagious activity of syphilis, and its susceptibility of hereditary transmission, ceased after three or four years, but there were well-authenticated cases in which it manifested itself as far removed as five or six years, and even later; that the precise date, in the evolution of the diathesis, when the limit of its contagious or transmissive power had been reached, did not admit of mathematical expression; that

this limit was materially influenced by the type of the syphilis, the character of the treatment, the presence or absence of certain conditions, etc., and that to fix the date at which a syphilitic man could marry with safety at three or four years, with or without treatment, and irrespective of the existence of specific lesions, was unwarranted by science or the teachings of experience.

The discussion was opened by DR. F. N. OTIS, who maintained that all the processes of syphilis were processes of growth, characterized by cell-proliferation non-inflammatory in character, and that when the contagious element had been removed the disease was at an end; that beyond the secondary period of syphilis, however long that may be proved to be present, there was no contagion; that all the lesions of the tertiary period of syphilis were free from the contagious element, and were simply sequelæ of the disease; that the period at the end of which marriage could take place with safety had, after thorough treatment, been fixed by the profession throughout the world as three or four years; that there should be, after thorough and prolonged treatment, an interval of a year or eighteen months, during which, without treatment, no syphilitic manifestation had appeared. These were statements in which all believed. For himself, he believed that the person was beyond the contagious stage of the disease at the end of three years, if proper treatment had been carried out. He claimed that, in view of the enormous mass of evidence presented, and of the general experience of authorities, wherever syphilis had been communicated at a period later than three or four years, it would be shown, in such cases, that the true source of the disease was in a lesion less than three years old.

DR. R. W. TAYLOR confined his remarks to three points: First, the length of the contagious stage of syphilis; second, can the arbitrary line be drawn upon one side of which it can be said that the disease was contagious and upon the other non-contagious; and, third, the course and contagious character of syphilis in its bearing on the question of marriage. The key-note to the contagiousness of syphilis could be summed up in the word treatment. If taken early, and treated thoroughly, the contagiousness, in ninety-nine out of a hundred cases, could be destroyed at the end of two or two and a half years. Of course, a papular syphilide might occur as late as the fifth or sixth year, and precocious tertiary lesions might be contagious; but these were very exceptional cases, and in them no syphilographer would think of permitting marriage. Again, there was no law that could be laid down as to the contagiousness and non-contagiousness of syphilis, uninfluenced by treatment. Each case, treated or not treated, must be considered by itself, with reference to all these important questions, and the question of marriage, if influenced by the decision of the physician, should not be decided until all these points had been most carefully studied. If circumstances be such as render postponement of marriage impossible, impregnation should be forbidden until the requisite length of time had been passed under treatment to destroy the contagiousness of the disease.

DR. E. B. BRONSON thought that there was nothing more uncertain in medicine than prognosis in syphilis. The uncertainty with reference to duration was exceedingly great, and it was impossible to say when the power to propagate the disease will have ceased. He was unwilling to believe that the disease was extinct because its manifest virulence had disappeared. There was no doubt, however, that there was a gradual diminution of the virulence of the poison of syphilis. He was also unwilling to admit that syphilis without symptoms may exist. He believed that treatment for three or four years should be adopted.

The discussion was closed by Dr. Morrow and Dr. Otis, who endeavored to reconcile some mathematical calculation concerning Fournier's statistics, and also some quotations from Dr. Otis' paper.

DR. F. R. STURGIS then read a paper on

THE SUPPOSED VIRUS OF THE CHANCROID,

in which he argued that there was no virus in this lesion, and that the supposed virus was really the result of acute inflammation. It was purely a local lesion, and its peculiarity was its capacity for auto-inoculation and its power for propagation.

DR. R. W. TAYLOR said that Dr. Sturgis' paper marked an epoch, as it was diametrically opposed to the summary of his article in the "International Encyclopædia of Surgery."

He was glad to have the support of his esteemed contemporary on a doctrine which was first enunciated by the late Dr. Bumstead, in a paper read in Philadelphia in 1876, and in the discussion of which he participated, and sustained the views of its eminent author by the results of his own independent observations. He was pleased to learn that the seed then sown had taken root, even at this late day.

DR. OTIS was entirely in accord with the author of the paper with regard to the non-specific character of the chancroid.

DR. E. B. BRONSON protested against the sweeping theory that the chancroid was the product of inflammation. There was an independent sore, and that independence implied a virus.

DR. TAYLOR said that deductions founded upon absolute facts could scarcely be classed as theories.

THE PRESIDENT cited a case of bubo following preputial herpes.

DR. STURGIS said that he wished to carry the view even further than had been done by Dr. Bumstead, and then the discussion was closed by Dr. Sturgis and Dr. Taylor in an endeavor to settle whether or not the views advanced in the paper were opposed to those published in the article in the "Encyclopædia of Surgery."

THE PRESIDENT called the Vice President, DR. DRAKE, to the chair.

DR. C. C. RICE read *the report from the delegates to the Medical Society of the State*, which was ordered entered upon the minutes.

DR. O. B. DOUGLAS then read the report of the special committee appointed to investigate

THE CHARGES OF THE PRESIDENT AGAINST THE BUREAU OF VITAL STATISTICS OF THE HEALTH DEPARTMENT.

The committee found that "physicians have had cause for complaint in the *manner* in which certificates have, at times, been returned for correction or alteration, and in the carelessness of clerks in requiring unnecessary changes in certain cases. In the judgment of the committee, when corrections are necessary the request for such should be sent to the physician by special messenger or under seal, and not a verbal demand be given the undertaker to be sent through friends of the deceased to the physician. All who have charge of issuing burial permits should be competent medical men, and be under special control of the superintendent, who could then be held accountable for their acts."

Signed by the whole Committee, Drs. Daniel Lewis (Chairman), John W. Warner, Wm. M. McLaury, John S. Warren, and O. B. Douglas (Secretary).

The report was adopted.

The Secretary announced the death of Joseph Cushman, M.D., February 15, 1887, and Louis F. Schultze, M.D., February 8, 1887.

Drs. Douglas, Johnson, and Drake called attention to the urgent necessity that all the members of the Society be at once active with their influence in favor of the passage by the Legislature of the bill known as

THE PURRINGTON BILL,

which was being opposed fiercely by quacks from the city of New York. The bill appeared in THE MEDICAL RECORD for February 26, 1887.

The Society then adjourned.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN SURGERY.

Stated Meeting, February 14, 1887.

ROBERT F. WEIR, M.D., CHAIRMAN.

TUBERCULAR SYNOVITIS OF THE SHEATHS OF TENDONS.

DR. A. G. GERSTER presented a patient whose case illustrated, in a striking manner, the possibility of treating successfully, by the aid of antiseptic surgery, affections which, previous to the work begun by Mr. Lister, were regarded as the *noli me tangere* of surgical art. In particular, the sheaths of tendons were not invaded with the knife, and therefore the special interest in the case presented, that of a medical student, twenty-five years of age, with good family history, who noticed, in November, 1884, on waking one morning, that he was unable to straighten the fingers of his right hand. Swelling and pain developed and increased on use, but subsided somewhat on giving the hand and wrist rest, yet the patient could extend the fingers only with considerable difficulty. On the whole, an increase of the swelling of the wrist was noticed.

In August, 1885, a similar condition developed, affecting the flexor side of the left hand, noticed first in the palm, gradually increasing in intensity, until finally the swelling appeared above the wrist, and the fact was soon established that the swelling on the flexor side of the forearm communicated with that of the palm of the hand.

The disease of the left hand and wrist was the more troublesome of the two, and his grasp was difficult and painful. He finally sought advice of Dr. Adler, who referred him to Dr. Gerster, who diagnosticated tubercular synovitis of the sheaths of the flexor tendons of the left hand and of the extensor tendons of the right hand, and advised operative treatment, as at that stage all other measures had failed to afford relief. Accordingly, on December 30, 1886, Dr. Gerster operated on the right hand. Although he had intended to operate on both hands on the same day, he was prevented from doing so by an urgent and important surgical case, and postponed the operation on the left hand until January 27, 1887.

The operation consisted in making a diagonal incision five and a half inches in length over the entire length of the swollen hand and arm, through the skin, fascia, and sheaths of the tendons. As soon as the sheaths of the tendons were incised, a yellowish, orange-colored fluid escaped, and it at once became visible that they were all very much thickened by a gelatinous material, soft and pearly in places, and in other parts rather opaque, and that the tendons themselves were covered, to a great extent, by the same material. In some places the tendon and its sheath were agglutinated to each other. One after another of the tendons was raised out of this bed, and the mass of gelatinous substance was completely removed. After each tendon and its sheath had been cleaned thoroughly, the physiological order was observed in uniting the wound, sheath with sheath, fascia with fascia, and skin with skin, and the limb then laid upon a splint and kept in an elevated posture. The operation was rendered bloodless by the Esmarch bandage, which is indispensable, and irrigation with a bichloride solution was kept up constantly. The wound was dressed antiseptically, and healed entirely by primary union. No febrile reaction occurred. The splint extended only to the base of the fingers, and the patient was directed to keep his fingers moving constantly. Doubtless the entire cavity filled with blood which became organized. The result had been *restoration of function completely.*

A similar operation was performed on the left hand, as stated, January 27, 1887. The dissection was much more difficult than it was upon the extensor surface, because it was necessary to divide the superficial part of the palmar arch, draw the branches of the ulnar nerve to one side, etc.; nevertheless, there was no serious difficulty in removing the mass. The only difficulty encountered was in releasing that portion of the tendons which passes underneath the transverse metacarpal ligament. Volkmann, who performed the operation twelve years ago, recommended the passing of a piece of heavy rubber drainage-tube under the ligament and forcibly seesawing until the whole was dislodged. Dr. Gerster tried this plan, but found that it was of no service whatever to him, and therefore he was obliged to dissect the soft parts close up to the ligament, incise a portion of the ligament, and then draw the tendons out. He finally succeeded in freeing the tendons from the mass completely by dissection.

Union of the wound was accomplished, as in the other operation, and the prospect was that the result would be as good as in the other hand. There was active extension and flexion, although not yet so free as in the right hand.

In both instances the first dressing was changed on the *tenth* day after the operation. Although there was no microscopical examination in this case, Koenig has already made it very probable that in all cases these masses are tubercular in character.

THE CHAIRMAN had been attacking these hygromata almost as heroically as had been described by Dr. Gerster, and had opened above and below, and scraped out thoroughly with the spoon for the purpose of dislodging the tubercular material. He had failed in several cases, as he had succeeded in several. The thoroughness with which the operation is performed, and the early movement of the fingers, he regarded as most important features of these cases. In several instances he had proven the material to be tubercular, bacilli having been found with the microscope.

DR. GERSTER had a similar case one year ago at Mount Sinai Hospital, the difference being that the affection was located on the extensor side of both hands. After delivery, for the woman was advanced in pregnancy, he operated on both sides at the same time, and the result was as good as in the case of the patient presented.

DR. V. P. GIBNEY presented a specimen [see p. 264] of

ACUTE EPIPHYSITIS OF THE HIP.

The cases which he had met with had been those in which the active stage had been passed, and all inflammatory conditions had subsided. English writers recommend early opening of the swelling, and then protecting the parts by mechanical appliances, so that the acetabulum can be saved. Generally the cases occur in children less than six months old, an abscess forms that finally opens, and then the damage has been done. At the beginning he would open the swelling freely and relieve the periosteum, and then put the limb in a good position and keep it fixed long enough to allow some kind of anchylosis to occur. At all events, such a plan of treatment would save the patient from the shortening.

These cases are frequently regarded as cases of congenital dislocation, and until someone happens to see a cicatrix. and then get the history, it might be so regarded and the case dismissed. But many of them can be traced to an acute process occurring early in life. The cases which are first seen in the late stage may give evidence by scars that there have been abscesses. There is only one case reported where it has been found that the disease was tubercular.

DR. A. B. JUDSON said that although the seat of the initial lesion and the structures subsequently involved are the same in acute epiphysitis and chronic osteitis of the hip, in acute epiphysitis there is an entire absence of reflex muscular contraction and rigidity of the joint, which are constant clinical features of the ordinary form of hip-disease. In the cases which he had seen not only were the muscles relaxed, but, in addition, the limb lay completely everted, reminding one of the position assumed in fracture of the neck of the femur in the adult, and suggesting the diag-

nosis of separation of the epiphysis of the head of the femur followed by suppuration and disease of the femur. But an injury of the joint, no matter how violent or extensive, is seldom followed by destructive disease of the bone. It may therefore be believed that some of the cases of so-called diastasis attended with suppuration are simply instances of acute epiphysitis.

After recovery from acute epiphysitis the joint is left in a condition very different from that which follows hip disease. There is shortening from loss of a portion of the length of the femur, as sometimes happens after hip disease, but instead of fibrous anchylosis, which is often the result of hip disease, there is, after acute epiphysitis, a remarkable degree of preternatural mobility, the hip-joint being as flexible, though strong and useful, as it is in congenital dislocation of the hip. In fact, the diagnosis is not always easy between congenital dislocation and the results of acute epiphysitis. If scars are present, there is an increased probability that the preternaturally mobile joint has been the seat of acute epiphysitis, and in the absence of scars it is not impossible that there may have been acute epiphysitis without an external discharge. In a case which he had seen several years after the acute stage, there was no scar, but a history was given of a purulent discharge from the vagina, which may have followed perforation of the acetabulum, as in the case of double hip disease reported several years ago by Drs. Poore and Gibney.

Dr. Jacobi asked how long the duration of the cases was before the formation of abscess.

Dr. Gibney replied that an average duration was from two to three weeks; they are acute, and soon come to the surface.

Dr. Jacobi would like to know whether or not there were cases which were less acute, even subacute, with but little fever and pain. If such cases occurred he could well imagine that internal treatment directed to the formation of bone, by means of the administration of phosphorus in small doses, in substance (not the phosphates or phosphites), might be of service. He had been in the habit of giving phosphorus internally in subacute and chronic bone disease of every description since seventeen or eighteen years ago, when Wagner described his well-known experiments in fractures treated with and without the internal use of this drug, and it had always appeared to him that the cases ran a shorter course when phosphorus was administered.

Dr. F. A. Castle then exhibited

A NEW SPICA BANDAGE

which he had been led to devise in the treatment of a case of gluteal abscess in which the ordinary spica failed to make the requisite amount of pressure and retain its position.

Dr. J. D. Bryant then read a paper on

MODERATE DILATATION OF A URETHRAL STRICTURE FOLLOWED BY ABSCESSES OF THE TRUNK AND LIMBS.

The patient was twenty-four years of age, and a merchant with good family history. There was no history of injury. He had had repeated attacks of gonorrhœa between 1875 and 1885, many of which were much prolonged. There was no positive history of gleet in the intervals, although it probably occurred. In 1883 the common symptoms of urethral stricture made their appearance, and in 1884 the presence of stricture was determined by a physician who cured it by gradual dilatation. The patient was rebellious not only this time, but at other times subsequently, and ceased treatment as soon as a comparative degree of comfort had been secured. At no time had the stricture been dilated above No. 13 English. There was also a history of repeated chills, followed or attended by fever, and associated with previous dilatation of the urethral stricture.

Under cocaine Dr. Bryant found a stricture three inches from the external meatus that admitted a No. 5 English bulbous bougie. At the bulbo-membranous junction was another stricture, which admitted only a whalebone guide, four of which were introduced side by side, and then dilatation was carried up to 5 and 8 of the conical gum-elastic bougie. This was done under cocaine, was performed without difficulty, and was attended by only a trifling amount of pain. The hemorrhage was only sufficient to discolor the mucus and oil that were expelled from the urethral canal.

Three days afterward Nos. 5 and 8 were introduced as before, without pain or difficulty. No. 10 encountered greater resistance than did 8 at the previous sitting, and some hemorrhage followed at the first micturition, when he had a chilly sensation attended with great prostration while sitting in the water-closet. During the next ten days he had irregular, chilly sensations and fever, and when Dr. Bryant, at the end of that time, saw him, the patient's pulse was 90, his temperature 102° F., and his countenance haggard. There were two phlegmonous swellings on the left thigh, one anterior, the other posterior, one above the crest of each ileum, a small one on the inner side of the right arm near the axilla, and a small one beneath the right nipple. Those on the thigh, and one of those above the crest of the ileum, suppurated profusely and discharged an abundance of offensive pus tinged with blood. The others disappeared soon afterward, except one, which remained for weeks, and then passed away without suppuration. The constitutional symptoms attending the suppuration were not severe, the temperature varying from 99° to 102° F., with occasional chilly sensations, without sweating, until near the close of the suppurative process. At this time the patient had a mild attack of pneumonia, with some pleuritic effusion, from which he made a satisfactory recovery.

The kidneys at no time gave any evidence of disease.

The most interesting and important feature of the case was the occurrence of phlegmonous swellings, and the question arose whether similar abscesses were consequent or accidental complications of the treatment of urethral stricture. If a consequent complication, how are they produced? Can they be prevented? Do they affect prognosis as regards cure and the life of the patient?

If an accidental complication, how are they to be avoided? It seemed to him that in this case they were accidental, or an indirect complication.

If they are a consequent complication of a septic nature, they must depend either upon the absorption of some poisonous element existing in the urine that comes in contact with freshened surfaces or on a subsequent thrombosis at the site of the stricture. If consequent on urinary sepsis, their prevention demands that the course of the urinary stream be changed, as, for instance, causing the urine to escape through an opening made in the perineum behind the site of the stricture.

He did not believe that urethral medication directed to the prevention of urinary sepsis by absorption was of practical importance.

If the phlegmonous swellings were accidental non-septic complications, no attempt at internal treatment should be made, provided the conditions of the case will admit of delay, until the patient has been thoroughly fortified, in a general sense, when either gradual dilatation or cutting can be resorted to—cutting, in his opinion, being the better of the two plans. Internal incision, if the obstruction be in front of the bulbo-membranous junction; external, if behind this part.

The Chairman said that Dr. Bryant's case was very interesting, and the complication described was a comparatively rare one, although not unique. He had met with the same conditions prior to the advent of antiseptic surgery, but recently had not had any urinary complications whatever. Multiple abscess, following urinary operations, slight or severe, dates back to Velpeau, who attributed them to a peculiar poison which comes from the urine or from a fault on the part of the surgeon. The

Chairman was convinced that it came from one of these two sources. We could guard our patients against it somewhat by the use of antiseptic injections at the time of the operation. He had more faith in this method than Dr. Bryant had expressed, and accordingly injected the urethra with a mixture of iodoform and sweet-oil, and always smeared the instruments with vaseline and iodoform. After the operation is concluded, he injects the bladder with a solution of bichloride, 1 to 10,000, and flushes the urethra as the instrument is withdrawn. In this manner he felt confident that he had made urethral absorption the exception rather than the rule. He had, in cases in which there had been a chill with rise of temperature, introduced a soft instrument and washed out the bladder and urethra.

Dr. F. N. Otis thought that Dr. Bryant was correct in his opinion that in his case the abscesses were only a coincidence. He had never met with a case in which abscesses occurred as the result of the manipulation mentioned or as the result of any urethral operation, although he had heard of such cases. His experience had been more in the way of dividing strictures than dilating them, and although it covered many hundreds of cases, he had yet to see the first abscess as the result. Rightly or not, he had attributed this immunity to the very great care which he had given to his instruments, passing them through an antiseptic solution before using them, perhaps through the flame of an alcohol lamp, carefully and thoroughly cleaning every instrument before it is put away, etc.

He had had but very little trouble from urethral fever, and had attributed this absence to the use of the catheter after the operation.

In those cases in which the patient has been accustomed to use the catheter or sound he always uses it, and in the cases where he had failed to use it, and the patient has passed his urine without the catheter, chill has frequently occurred, perhaps for the first time three to five days after the operation. It seemed to him that the catheter was one of the best means of preventing urethral fever.

He had also found that urethral fever had been prevented by quinine, and therefore he uses the remedy after his operations. He had not practised irrigation of the bladder as carefully as the chairman had mentioned, although in cases where habitual disinfection was required, on account of decomposition of the urine, he had been very careful to wash out the bladder; but where it was in good condition he had not thought that it was necessary. He had avoided operating where a urethral discharge was present, and had taken pains to have the patient lay up until at least the discharge was reduced to the least quantity and there was no pain. In cases where it had been impossible to reduce the discharge so that it was not painful, he had kept up the use of antiseptic injections after the operation.

The Chairman asked Dr. Otis if there had been much pain produced by introducing the catheter early after internal urethrotomy.

Dr. Otis said that he had very seldom found that it produced pain. Sometimes there was difficulty in introducing it on account of coagulated blood in the urethra, and he had taken pains to dislodge the clots of blood, but where there had been much difficulty he had allowed the patient to urinate rather than attempt to pass the catheter.

Dr. F. R. Sturgis thought that there was no sepsis at all in Dr. Bryant's case. He would suggest the possibility of the presence of sugar in the urine, and that suggestion he based on the history of a single case only that had fallen under his observation. In the event of sugar being in the urine, he would decline every operation except perineal section. In Dr. Bryant's case, whether the urine were diabetic or not, he would perform only the perineal section, as he thought it quite probable that there would be a return of the difficulty if he attempted to dilate. He thought that the Chairman was over-cautious in washing out the bladder and flushing the urethra, although cleanliness in the highest degree was commendable.

With regard to the use of quinine, he gave it his most hearty adherence, and believed that it would prevent a chill in nine out of ten cases, giving five grains two or three hours before the operation, and nine grains with one grain of opium after the patient had come from under the influence of the anæsthetic.

Concerning the use of the catheter, he thought that in the larger portion of cases the patients were as well off without as with it. According to his experience, the introduction of the catheter had been painful. He also favored sudden dilatation to the cutting operation, and had practically abandoned internal urethrotomy on account of the chill, hemorrhage, etc., liable to follow. Certainly his experience had been unfortunate in urethrotomy for deep strictures, for which he now always performs perineal section.

Dr. R. W. Taylor agreed fully with the Chairman with regard to the use of quinine, and in the main with reference to the antiseptic precautions. He believed, however, that it was best to treat urethral stricture by dilatation when it was possible to do so. Some years ago he had a case in Charity Hospital in which he operated with Maisonneuve's instrument, which he preferred to the divulsing instrument of Holt, and the patient had phlegmonous inflammations in the thighs, arms, and trunk.

He also called attention to a case of septic absorption from the urethra after a cutting operation.

Dr. Castle said, with regard to antiseptic applications to the urethra, that vaseline, cosmoline, etc., really belonged to the paraffines, which vary very much as to solidity. Paraffines can be obtained which are limpid and also free from rancidity. Olive-oil should never be used in making antiseptic solutions, unless the antiseptic is sufficiently powerful to disinfect the oil itself, which is almost invariably impure.

Dr. Otis said that he had been using the liquid forms of paraffine with great satisfaction. He had always used quinine in the form of suppositories—ten grains of the bisulphate with one-quarter of a grain of morphine immediately before the operation.

The Chairman said that he had fallen back to the use of the tincture of aconite, three minims two or three times a day, but always with morphine. All use more or less of morphine after these operations, and he thought it quite probable that the benefit came from the morphine rather than from any of the drugs with which it was combined.

Dr. Bryant said that the urine in his case was not examined until after the recurrence of the chill. It did not contain sugar, and the kidneys had not given any evidence that they were diseased.

With regard to the use of quinine, he had given it in the different ways and in varying doses, and he had reached the conclusion that it did not exert any salutary influence. He also used oil combined with carbolic acid or iodoform for urethral injections. With regard to dilatation, divulsion, and the cutting operations, he was inclined to think that, when his patient was in a proper condition for another operation, he should first wash out his urethra carefully, and if a chill followed, he should cut his stricture and allow the patient to take the chances.

Dr. Castle suggested that there might be some disturbance of the trophic nerve-centres in Dr. Bryant's case to account for the trouble. If so, any operation would be liable to be followed by such a history as had been given.

Dr. R. W. Taylor then read a paper on

THE RELATION OF FIBROMATOUS INFILTRATION OF THE SKIN TO KELOID,

which was really a sequel to his paper published in the *Journal of Cutaneous and Genito-Urinary Diseases* for February.

The present contribution pertained to the *etiology*. Traumatism he believed to be an important cause of moluscum fibrosum, and he cited two cases to sustain the opinion, in which the wounds were sufficiently severe to damage the subcutaneous layer. In the fibromatous tumors there is no tendency to recurrence after removal, which is unlike keloid.

The Chairman referred to two cases of keloid *without* the spur-like processes.

Dr. Taylor exhibited an illustration of hyperplastic cicatrices. True keloid disease originates in superficial irritation, and is essentially different from hyperplastic cicatrix.

The Chairman asked Dr. Taylor concerning the character of the little tumors which appear at suture holes sometimes and are so annoying.

Dr. Taylor said that his studies had convinced him that keloid varies less from the typical form than any other variety of connective-tissue new-growth. The confusion which surrounds it is due to the fact that the various forms of hypertrophic or hyperplastic cicatrices are classed as keloid or fibro-keloid. The word keloid should be used only in the sense meant by Alibert, for circumscribed patches of shiny, pinkish elevations of the skin from which claw-like processes jut out as do the claws of a crab. Wherever this condition is seen, be the origin spontaneous or due to traumatism, the term keloid should be applied. When hyperplastic or hypertrophic processes invade scars, points of suture, and lines of incision, and are limited to their area, they should be called hypertrophic cicatrices. Should they show a tendency (as they sometimes do) to extend by claw-like out-shoots, then they come within the meaning of keloid.

The Section then adjourned.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, February 1, 1887.

C. L. Dana, M.D., President, in the Chair.

Dr. C. L. Dana reported a case of

PACHYMENINGITIS HÆMORRHAGICA, WITH LARGE MENINGEAL HÆMORRHAGE PRESSING CHIEFLY ON LEG-CENTRE—RIGHT HEMIPLEGIA, TOTAL PARALYSIS IN LEG, APHASIA, HEMIANÆSTHESIA, CONVULSIONS LIMITED TO ARM AND FACE.

The patient was a woman about sixty-eight years old, and came into the hospital with complete motor aphasia, and unable to give any previous history. She had no paralysis at first, but three days after admission she had a general convulsion, followed by right hemiplegia—total in the leg, and some right-sided anæsthesia. On the second and third days she had a series of brief localized convulsions, involving the face bilaterally and the right arm. These were carefully observed. The movements were clonic, beginning in the muscles of the lower jaw. The other peculiarities were these:

1. The pupils remained small during the convulsions. When wider convulsive centres are discharging, as in general epileptic convulsions, the pupils are dilated.

2. The conjugate deviation of the eyes was at first, and very temporarily, toward the side of the lesion, and away from the paralyzed side. The head also was turned toward this side. When this occurs it is ordinarily spoken of as a paralytic deviation. This does not explain it here, since almost immediately the head and eyes were turned strongly to the opposite and paralyzed side. The speaker suggested that the first deviation is due to an inhibition of the activity of the associated nuclei of the third and sixth nerves that innervate the external and internal recti of the two eyes. There are many facts which tend to show that the first stage of convulsion is a transient paralysis, due to a sudden discharge of inhibition centres. These are of a higher, more developed class than the centres for motor discharges, and would be affected first. We would have then loss of consciousness, inhibition of motion and muscular relaxation; then motor discharges and tonic and clonic convulsions.

3. The temperature on the paralyzed side was one degree higher than normal, and higher by a degree than that of the other side. This is the rule in intra-cerebral hemorrhage and hemiplegia; but the speaker was not aware that it has been established in cortical hemiplegias. In meningeal hemorrhages the temperature is often below normal, according to Minot.

4. The presence of hemianæsthesia.

The patient died on the third day. Post-mortem showed chronic pachymeningitis over both convexities, but more on the left side. On the left convexity there was a very extensive, fresh meningeal clot, pressing upon and flattening especially the upper half of the central convolutions. Brain-substance normal.

CORTICAL EPILEPSY WITH TEMPORARY APHASIA—SYPHILITIC GUMMA COMPRESSING THE LEFT SECOND FRONTAL CONVOLUTION IN ITS LOWER POSTERIOR PART—RECOVERY.

Dr. M. Allan Starr related the history of the case. Charles S——, thirty-two years of age, had always been healthy and a hard worker. He had an attack of sciatica four years ago, and three years ago had a hard chancre. He had never had convulsions or nervous affection. Family history good. During November, 1886, and the first two weeks of December he did not sleep well, was slightly dizzy, his head ached a good deal, chiefly at night. December 15th, while walking with a pail in his right hand, he suddenly let it drop, losing all power in the hand and arm. There was numbness in the hand. He was unable to speak to his companions. He did not feel dizzy nor notice any pain in the head; he did not lose consciousness nor fall. He understood his friends' questions, but could not answer. Power in the hand and arm, and speech returned within half an hour. The next morning he went to work, as well as usual. Two days later a second attack occurred, beginning with a numb feeling in the tips of the fingers, gradually extending up the hand and arm. Then the fingers became rather forcibly flexed and stiff, but by a voluntary effort he could straighten them. No clonic spasms of the fingers, and wrists and elbow were not bent. The numbness and stiff feeling soon extended to the face, which was drawn to the right side with some force. Speech was again lost. No loss of consciousness. The attacks lasted about twenty minutes. Such attacks had occurred every other day, then every day, and finally thrice a day up to January 3d. Examination by Dr. Starr showed slight paresis, and slight tactile anæsthesia in right hand; no affection of face or speech. The diagnosis was reached of gumma in the membranes, resting upon the main surface, giving rise to irritation and consequently to an occasional nervous discharge, but not of sufficient size to cause any destruction. Location of tumor was equally clear; the relative situations of the cortical centres for the arm, face, and for the movements of speech in the lower two-thirds of the anterior central convolution and in the posterior part of the third frontal convolutions were likened to a reversed L. All these centres were irritated during the attacks, the irritation sometimes beginning in one, sometimes in another.

The treatment ordered was, first, inunction of mercury, and, second, iodide of potash daily, in divided doses. He had one attack two days after beginning treatment, but since that time he had had no return of the symptoms. Iodide of potash was still being taken.

DISCUSSION ON DR. STARR'S PAPER.

Dr. Seguin had seen several cases whose symptoms resembled those of the case recorded in Dr. Starr's paper. The prognosis of even non-syphilitic cortical lesions with this symptomatology was not absolutely unfavorable.

One of the cases to which he referred was that of a Cuban who came to his clinic about nine years ago. He had never had syphilis, yet he described epileptic attacks of the true cortical kind, such as have been obtained by experiments upon animals during the last few years. The hand would become numb, and then the seat of a vibratory sensation; finally, contraction would occur in the hand, when the face, and almost simultaneously the leg, would be affected, and he would lose consciousness. According to his friend's account general convulsions then occurred. He had had quite a number of these seizures; yet examination showed no anæsthesia, no affection of the optic nerve, and, so far as the speaker could recollect, no motor impairment. The patient had received a preparation composed mostly of the bromide of potassium, to which a little of the iodide was added. He improved immediately, and four years ago the attacks ceased.

The patient had also been the object of the bracelet experiment. He was a powerful man, and had exerted great force, arresting many attacks in this way. The speaker was satisfied that syphilis was absent, while the amount of the iodide was too small to explain a cure upon the ground of a syphilitic affection.

Dr. Shaw referred to a case seen first four years ago. While at work as a jeweller the patient fell off his bench in a convulsion. The face and the left arm were convulsed; the leg was not affected; sometimes only the side of the face was affected. He had seen many of these attacks limited to the side of the face in his office. The patient complained of numbness in the arm and the side of the face, and the speaker felt sure that the tactile sensibility was not as good upon that as upon the other side. The patient denied syphilis. Upon ophthalmoscopic examination the nerves were found pale, and the visual field restricted in its upper part. There was no change until about six months ago, when, without loss of vision. he was found to have choked disk. This had gone on to atrophy, and the man was now blind; there was no paralysis. From the choked disk, of course, the speaker had now diagnosed a tumor, but he referred to the case on account of the anæsthesia and the spasms and their resemblance to those in Dr. Starr's case.

Dr. Sachs referred to the case of a man who, some years ago, while working upon the capitol at Albany, had fallen some distance, was found unconscious, but recovered. A few weeks later he developed symptoms which alarmed his friends, and he had now some of the physical and nearly all of the mental signs of general paresis; the irregular pupils, the facial tremor, the tremor of the tongue, and the deteriorated mentality. Every three or four weeks this man had an attack of numbness, beginning in the fingers and creeping up the right arm to the face. There never were convulsions.

Dr. Dana thought that cortical epilepsy might develop like idiopathic epilepsy, without an appreciable lesion. He recalled a case, that of a young man who was kicked in the front of the thigh by a horse; clonic spasm of the leg developed, similar to that of cortical epilepsy. Thrilling and numbness of the arm and face followed. In three or four years true hemieleptic attacks, during which he lost consciousness, developed; most of the time he had only the leg convulsions. There was no history of syphilis. Apparently cortical epilepsy was developed, just as true idiopathic epilepsy in other cases.

Dr. E. C. Seguin read a paper entitled

A CONTRIBUTION TO THE PATHOLOGY OF THE CEREBELLUM.

A detailed account of one case was given, and specimens, gross and microscopic, illustrating its pathological anatomy, were shown. Three other cases of cerebellar disease were briefly presented, as card specimens with their anatomical demonstrations. The following is a summary of case one: Male patient, forty-five years old at time of death; a retired officer of the United States Navy. Eighteen years before death illness began with headache, not strictly occipital, and one or more seizures of an epileptiform or apoplectiform character. These were followed by impaired vision and more or less continuous headache—fronto-occipital. Later appeared nystagmus and typical cerebellar titubation; slight slowness of speech. There was no distinct paralysis, true ataxia, anæsthesia, vertigo, or mental impairment. During several years, from 1877 to 1883 or 1884, the only symptoms were slight frontal headache, defective vision, partial atrophy of both optic nerves, nystagmus of varying form, slight slowness and indistinctness of speech, increased patellar reflex, and titubation.

In February, 1885, an epileptiform seizure left behind it partial left hemiplegia without contracture and anæsthesia. Death on April 22, 1885, preceded by a set of distinctly bulbar symptoms; increased dysarthria, dysphagia, salivation, polyuria; also increasing stupor.

Lesions cyst of cerebellum, destroying the caudo-ventral part of the middle lobe—not involving frontal third of the vermis superior, penetrating into the right lateral lobe as far as the nucleus dentatus—not destroying it, and probably exerting only slight pressure upon the floor of the fourth ventricle. There were also found: 1. A small hemorrhagic focus two inches in diameter in the ventral half of the pons on the right side, in the midst of the pyramidal fasciculi. This explained the left hemiplegia, and from it, caudad, could be traced a complete descending degeneration of the right pyramidal tract into its subdivisions in the spinal cord. 2. Very extensive arteritis obliterans of the encephalic vessels, causing numerous—mostly symmetrical—foci of softening in the cerebral hemispheres. The only system-degeneration which could be traced to the loss of substance in the cerebellum was a moderate reduction in the size of the opposite left olive and partial atrophy of the right restiform body.

The author called attention to several conclusions to be drawn from a study of these four cases:

1. As to diagnosis. Tumors of the cerebellum produce very variable symptoms; but one symptom, viz., cerebellar titubation, is, as claimed by Nothnagel in 1876 or 1877, pathognomonic of a destructive lesion of the middle lobe of the cerebellum, more especially its caudo-ventral masses. In Dr. Seguin's cases optic neuritis or atrophy had not failed, which was in marked contrast to his experience with tumors of the cerebral hemispheres, which do not usually cause lesion of the optic nerves (1 to 5 or 1 to 4). Vomiting was a frequent symptom; occipital headache and rigidity of muscles of the back of the head were less frequent, but very valuable symptoms.

2. As to therapeutics, three of the patients had obtained repeated relief from serious symptoms—paroxysms of headache, vomiting, and epileptiform attacks—by the use of iodide of potassium in doses of from thirty to sixty grains three times a day.

3. As to prognosis, two of the patients did not die of their cerebellar disease (both cysts), but of complications; Case 1 of diffused arteritis obliterans and consequent softening in various parts of the brain (including impaired nutrition of the bulbar nuclei); the other case, No. 2, of an acute tubercular meningitis. Consequently we may hope, in a few cases, to cause or to witness an arrest of the cerebellar disease. The disorder in voluntary movements and the already developed lesions of the optic nerves are of course irremediable.

Dr. Bradner spoke by invitation. He had been the attendant in the case of the child to which Dr. Seguin had referred. He had not prescribed the washing out. It had been done by a prominent physician of the place. He had done it a number of times during three weeks, but had then refused, believing that the child had brain disease of some form. He saw the patient first in November. The vomiting was always in the morning. There was no pain connected with it then, although a frontal headache had developed during the last few months.

Dr. Putnam-Jacobi referred to the recent collection of cases by Bernhardt. All cases published previous to 1884 had been collected by Nothnagel. Dr. Seguin's cases tended to confirm Nothnagel's laws. There were many resemblances between the symptoms of cerebellar tumor and those of tumor in other parts of the brain. The peculiar violence of the headache and the choked disk found in most cases of cerebellar disease might, she thought, be due to the increased pressure of a tumor confined by the tentorium. This element had not been commented upon, and she would like Dr. Seguin's opinion upon it.

Another point referred to the fact that the laws formulated by Nothnagel recognize the possibility of complete latency of the tumor, no symptoms at all being present when but one lobe of the cerebellum is affected, such symptoms appearing only when the tumor encroaches upon the central lobe. In one of Dr. Seguin's cases the tumor occupied the lateral lobe. Of course an indirect affection of the central lobe might be present even in such a case.

Dr. Leszinsky referred to a case to which he was called in consultation by Dr. Alexander. The boy had the typical gait of spastic paraplegia; any attempt to stand caused spastic contractures in the limbs. The ankle-clonus was present, and the knee-jerk was exaggerated. Later tremor developed, and paralysis of the abducens, of the fifth, and of the third nerves. Total blindness occurred. The nurse, a graduate of Bellevue, was positive that the child could see nothing. It died in a convulsion. Unfortunately the body was immediately frozen, and the specimen was unfit for sections. The tumor was found occupying one side of the cerebellum.

Dr. Starr had had occasion some time ago to make a collection of cortical lesions from American literature. He had at the same time made a collection of cases of cerebellar disease from the same sources. As the data obtained but corroborated Nothnagel's results, he never published them. But Dr. Seguin having remarked upon the value of corroborative evidence, he would briefly refer to them now. From 1860 to 1884, 160 cases of cerebellar disease were reported in American literature. In only 40 of these were the symptoms and the autopsies described with sufficient accuracy to warrant conclusions. These 40 the speaker had quite thoroughly analyzed. In 4 there were no symptoms; in one of these there was congenital atrophy of the cerebellum, in 2 abscess, and in 1 a large cyst. Of the remaining 36 presenting symptoms there was headache in 36; inco-ordination in 25; vertigo in 20; vomiting in 18; blindness in 14; dim vision in 6; diplopia or strabismus in 7; deafness in 7; facial spasm or paresis in 4; hemiplegia in 9; general paralysis in 4; mental symptoms in 8; stupid, 7; mania, 1; convulsions in 7; sexual desire increased in 2. Males, 23; females, 17; ages, between one and twenty years, 11 cases; between twenty and forty years, 16 cases; between forty and sixty years, 9 cases; over sixty years, 1 case; age not stated in three.

In 2 of the 11 cases in which inco-ordination did not occur the lesion probably involved the middle lobe. In cases where inco-ordination occurred various parts of the cerebellum were involved, but the probability was that the middle lobe was affected in the majority. There were only 2 instances of increased sexual desire. Bernhardt had found but 1 instance in 90 cases of cerebellar tumor, and Nothnagel but two cases. The speaker thought that it might be thrown out as a symptom of cerebellar disease, and regarded as one of accidental occurrence. The escape from vertigo in Dr. Seguin's case was explained, perhaps, by the recent discoveries in the anatomy of the course of the acoustic nerve. This nerve served for the sense of hearing and the sense of space. The centre for hearing is in the pons. Edinger finds the centre for equilibrium in the cerebellum, to which acoustic fibres pass by way of the middle peduncle. From this centre the central tract probably passes onward to the superior peduncle. Dr. Seguin says that the superior peduncle escaped in his case. It is therefore natural that vertigo should not have occurred.

The tendency to rotation was an interesting feature in these cases. There was a tendency to fall or turn forward in 2 cases; the lesion was in both a tumor in the vermis in the anterior part. There was a tendency to fall to the right in 2 cases, in one there being a tumor in the left middle peduncle and in the other an abscess in the same part. There was a tendency to fall to the left in 2 cases, in one there being an abscess in the right middle peduncle and in the other a tumor in the left middle peduncle. A patient of Nothnagel, whom the speaker had seen in Vienna, when getting up in bed had always a tendency to turn to the right side. Nothnagel considered this due to vertigo. It was only present when the patient was erect. The patient felt as though about to fall to the left side, and hence turned to the right. This case had a tubercle of the left middle peduncle of the cerebellum. Nothnagel considered this symptom only produced by affection of the middle peduncle. In the two cases in the table where the tendency was to turn to the right, there was disease of the left middle peduncle; while in the two in which the tendency was to the left, in one the right peduncle and in the other the left peduncle was affected. No rule can therefore as yet be laid down as to the cause of this symptom.

Dr. English had had charge of the case which formed the subject of Dr. Seguin's paper, and he congratulated the Society upon the progress which had been recently made in the diagnosis and treatment of cerebellar disease. Early in 1878 Dr. Seguin had written him a letter, accurately diagnosing this case as seen on autopsy.

Dr. Seguin closed the discussion. He was not surprised to learn of the little boy's fall, as he was a firm believer in the traumatic origin of these conditions. It was very difficult to obtain a history of fall. He could not give an opinion upon the question propounded by Dr. Putnam-Jacobi. In regard to ascribing the vertigo to the acoustic nerve he was not yet certain that the acoustic nerve had cerebellar origin. He thought it would be difficult to trace fibres through the lateral peduncle of the cerebellum, the vermis, and the anterior peduncle.

OUR LONDON LETTER.

(From our Special Correspondent.)

PAROTITIS AFTER ABDOMINAL AND PELVIC LESIONS—INDURATION OF PRIMARY SORES IN WOMEN—ACTINOMYCOSIS IN MAN—COCAINE IN DENTAL SURGERY—A NEW SPECIAL HOSPITAL.

London, February 14, 1887.

At the last meeting of the Medical Society of London the greater part of the time was occupied with the reading of a lengthy paper, by Mr. Stephen Paget, on "Parotitis after Injury or Disease of the Abdomen or Pelvis." Mr. Paget is a younger son of the eminent surgeon, Sir James Paget, Bart., and the only one who has entered the profession, his elder brother being a clergyman in the Church of England. He is already known as a rising young surgeon by his published papers on various surgical topics. His recent paper may be regarded as a continuation or expansion of one published by him in *The Lancet* last year, in which he gave particulars of 60 cases of secondary inflammation of the parotid. He now brought forward 101 cases, all of them being secondary to abdominal or pelvic disease or injury. The antecedent diseases or injuries of other organs were distributed as follows: Of the urinary tract, 10 cases; of the alimentary canal, 18; of the abdominal wall, subperitoneal or peritoneal tissue, or peritoneum, 23; of

the generative organs (including temporary derangements, such as slight injuries, menstruation, etc.), 50 cases. Parotitis, when occurring after injury of the extremities, was always part of a general pyæmia. But, when occurring after abdominal or pelvic lesions, it was, in 93 of 101 cases he had been able to collect, an isolated event unaccompanied by any other inflammation. In only 15 of the cases was there distinct mention of "septic symptoms," "septicæmia," or "pyæmia." Thirty-seven cases died, but of these 3 were over eighty, 3 had cancer, 2 had perforation, 2 had strangulated hernia. Among the remaining 27 were cases of acûte peritonitis, severe injuries, septicæmia, or pyæmia. The danger was thus not in the parotitis itself, but in the primary lesion causing it. This form of parotitis had no period of incubation. It had been observed on the first day after the primary lesion, on the nineteenth, and on the intermediate days. In one case it came on on the morning of the day fixed for an operation. When due to abortion or delivery, it seemed to come on later than when due to operations on the generative organs. The onset of this form of parotitis was rarely attended by much general disturbance. Rigors occurred in 4 cases; delirium or puerperal mania in 6. In most cases there was only a slight rise of temperature and no rigor. In only 78 of the cases was the termination of the parotitis recorded. Forty-five of these went on to suppuration. Of this number 24 died and 54 recovered. Thirty-three ended in resolution, with only one death among them, and this was the case of a patient with cancer. Mr. Paget remarked that as to the fatal cases of suppuration, they died, not because the parotitis went on to suppuration, but that this took place because they were going to die. The author concluded by discussing the various theories of the causation of the parotitis in these cases and did not admit that any one of them was entirely satisfactory.

Considerable interest was aroused at the Medical and Chirurgical Society on Tuesday last by the reading of a paper, by Mr. W. E. Cant, entitled "Some Clinical Observations on Induration in the Primary Lesion of Syphilis in Women." The paper was based upon some three three thousand odd cases observed by the author while Resident Medical Officer at the Royal Albert Hospital, Devonport. The observations made extended over a period of between six and seven years. Induration of the primary lesion in women is generally admitted to be rare, but Mr. Cant's observations would show that it may in many cases be found when sought for. In women, he said, induration (when present) was not infrequently diffused a considerable distance into the tissues around, often very widely, not sharply defined from the surrounding tissues, nor circumscribed in the base of the sore itself. The character of the induration therefore differed widely from that of primary sores in men. The typical form of primary indurated sore in men (resembling a disk of cartilage set in surrounding soft structures) was rare in women. Every variety as to the degree of development of induration was met with in women, but in about one-third of the cases it was very slight. In a small number none existed throughout the whole course of the sore. Induration might occur at almost any period of the course of a sore. In only a few cases was it present in the early stage; in many cases it became most marked and developed toward the middle and latter part of the case.

Dr. Drysdale agreed with Mr. Cant that induration was much less common in women than in men, and remarked that the occurrence of induration might be influenced by the different condition of the genital organs in the female. In a hard chancre of the lip in a woman the induration might be "wooden." Even in the male many cases might exhibit but slight induration. As to the situation of the primary sores on the female genitals in his own experience out of 241 cases four-fifths occurred on the labia majora and minora. The initial hard sore might occur on the os uteri. He had not seen one on the vagina. Several speakers joined in the discussion. Mr. Cant, in his reply, observed that he had seen two chancres on the os uteri, one on the vagina, and some on the buttocks.

Mr. Cant's paper was followed by one by Dr. Hebb, in which he related the history of a case of actinomycosis in man, and described the morbid appearances found after death. In the discussion on this paper Dr. Theodore Acland remarked that the disease was not nearly so rare in man as it had been supposed to be. He had himself seen four cases, and about thirty cases of disease of the lung in human beings had been reported in Europe. The disease was very common in cattle.

A well-known dental surgeon, Mr. Morton Smale, has been making some further experiments with cocaine in relation to dental surgery. Previous experiments had not caused him to form a very high opinion of its value, but more recent investigations with stronger solutions have led him to view it more favorably. He now uses solutions of from ten to twenty-five per cent., and has employed it successfully for extractions, torsion of misplaced teeth, removal of live pulp, and to deaden the pain caused by wedging teeth apart for stopping purposes.

We are threatened with another special hospital. It is to be devoted to the treatment of diseases of the throat, ear, and nose, and its promoters have bestowed upon it the designation of "The London Throat Hospital." I understand its medical officers will consist chiefly, if not entirely, of those gentlemen who withdrew from the Hospital for Diseases of the Throat in Golden Square last spring, in consequence of the attitude of the Committee and of Dr. Morell Mackenzie. Six physicians and surgeons then resigned, and four at least of these are about to join the new venture. Rumor has it that they have founded the new hospital as "a rival show" to the old one. One or two outsiders are joining them, and some money has already been collected.

ADMINISTRATION OF QUININE IN BRONCHO-PNEUMONIA.

To the Editor of The Medical Record.

Sir: A recent discussion on "The Administration of Quinine in the Treatment of Broncho-Pneumonia in Children," by the members of the Northwestern Medical and Surgical Society of the City of New York, is remarkable, not only for what it contains, but equally so for what it does not contain. It indicates a decided modification of the views of some of the members, at least, who, in their writings in the recent past, strongly advocate the use of large doses of quinine for the so-claimed antipyretic effect.

On this occasion there was not a single voice raised in favor of giving large doses, while nearly every speaker confessed to the use of tonic doses only. The very great trouble met with in giving, even the tonic doses of quinine, was pictured very forcibly in the "fights" and "rows" necessary to compel the unwilling children to take the bitter drug; and the lamentable part was that, after so much labor, the rebellious stomach would almost certainly reject the medicine. One member had tried rectal suppositories, but another condemned that method as almost useless.

The method that seemed to meet with most favor was to disguise the unpleasant taste in syrup of wild-cherry; but anyone who has tried this combination well knows that it is not so very palatable that "children cry for it." Judging from the discussion referred to, the problem, "How to give quinine to children," would seem to be still unsolved.

I am surprised that the way out of this difficulty did not at once occur to almost every member of the Society. It was a singular oversight; and I am sure no one will be more surprised than they themselves, when they recall

the ease with which the difficulties of giving quinine can be overcome. For some years I have not attempted to give quinine to children by the mouth. The most simple and satisfactory way is by inunction with the *oleate of quinine*. It is an elegant and definite preparation, occasions no struggle in administration, and there is not the least danger of its rejection by vomiting.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from February 20 to February 26, 1887.

TESSON, LOUIS S., Captain and Assistant Surgeon. Ordered for duty as Attending Surgeon at Headquarters, Division of the Missouri, and Examiner of Recruits at Chicago, Ill. S. O. 44, A. G. O., February 24, 1887.

BARROWS, CHARLES C., First Lieutenant and Assistant Surgeon. Resignation accepted by the President, to take effect February 17, 1887. S. O. 42, A. G. O., February 19, 1887.

BLACK, CHARLES S., First Lieutenant and Assistant Surgeon. Ordered from Fort Clark, Tex., to Fort Davis, Tex. S. O. 23, Department of Texas, February 18, 1887.

MASON, CHARLES F., First Lieutenant and Assistant Surgeon. Resignation accepted by the President, to take effect March 25, 1887. S. O. 44, A. G. O., February 24, 1887.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 26, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	8	4
Scarlet fever	52	14
Cerebro-spinal meningitis	3	2
Measles	225	28
Diphtheria	82	23
Small-pox	21	2
Yellow fever	0	0

THE CONDITION OF THE LARYNX IN WHOOPING-COUGH.—Dr. Von Herff, while suffering from an attack of whooping-cough, made a series of observations on the appearances presented by his own larynx in this disease (*Deutsches Archiv für klinische Medizin*). He examined his larynx throughout the whole course of the disease, sometimes even during the attacks of spasm. The results of his observations were as follows: Throughout the whole course of the illness a slight degree of inflammation of the mucous membrane of the respiratory tract was seen to exist, extending from the posterior nares to the bifurcation of the trachea. In the earlier stages this inflammation took the form of a slight catarrh, but during the spasmodic stage it was very intense and widespread, and only slowly disappeared during convalescence. The intensity of this inflammation varied in different parts of the respiratory tract. It was specially well-marked over the mucous membrane covering the arytenoid cartilages and the cartilages of Santorini and Wrisberg, but was greatest over the back wall of the larynx between the vocal cords, as well as on the under surface of the epiglottis. The other parts of the larynx remained unaffected, the vocal cords themselves being quite intact. The hyperæmia, however, extended into the trachea, and could be distinctly seen as far down as the bifurcation. It was found that during every paroxysmal attack a small pellet of mucus could be seen lying on the back wall of the larynx, on the level of the glottis, on the removal of which the attack instantly ceased. Further, by irritating this part of the larynx by means of a sound, a spasmodic attack of coughing could be induced, simulating in every way the attacks of whooping cough. Irritation of the under-surface of the epiglottis had a similar, though less marked, effect. On the other hand, stimulation of other parts of the larynx was entirely without effect in producing the characteristic paroxysms of coughing. He is therefore of opinion that the inflammation of the mucous membrane in this interarytenoidal region is specially connected with the peculiar attacks of spasm in whooping-cough.

A SURGEON AND ARTIST.—In the current volume of "St. Thomas' Hospital Reports" there is an article by Mr. William Anderson, Assistant-Surgeon to St. Thomas' Hospital, which give a most interesting outline of the history of art in its relation to medical science. Mr. Anderson is one of the many accomplished members of the medical profession whose art studies form the relaxation and chief pleasure of a laborious scientific career. Few, however, have ever combined in an equal degree the accomplishments of an anatomist and surgeon with those of profound erudition, conscientious research, and refined artistic taste. Mr. Anderson's great work on the "Pictorial and Glyptic Arts of Old Japan" is unique in European literature, and we are glad to see that its high merits have recently been fully recognized by such important organs of opinion as the *Quarterly Review* and the *Times*, as well as by the leading art and literary journals on the continent. On the subject of Japanese pictorial art he may justly claim to be the first living authority, and he has been the pioneer in the study of the pictorial arts of the great schools of the far East, which possessed, until recently, masters like Kanaoka, Motonobu, Tanyu, Okio, Hokusai, and Sosen. The works of these artists, which are still rare in Europe, may fairly compare with those of Cimabue, Velasquez, Snyders, and Landseer. In the present article Mr. Anderson reviews the services rendered by art to science in the elucidation of anatomy and pathology. Beginning with a reference to the anatomical studies of Leonardo da Vinci and Raphael, he passes on to the great work of Vesalius, "Humani Corporis Fabrica," which was illustrated by the pupils of Titian; to the Amsterdam folio on the anatomy of the human body, by Bidloo; to the "Tabulæ Anatomicæ" and other anatomical works of J. Casserius and Spigelius, illustrated by Fialetti; to the finely illustrated "Osteographia," of Cheselden; the "Tabulæ Sceleti," of Albinus; and the "Anatomia Uteri," of William Hunter.—*British Medical Journal.*

THE LAW OF THE DETERMINATION OF SEXES; KISCH'S MODIFICATION OF THE HOFACKER-SAELLER LAW.—When the husband is at least ten years older than the wife, and when at the same time the wife is within the age of highest reproductive power (twenty to twenty-five), there will be a very distinct excess of boys born over girls. This excess will be marked, but less distinct, when the husband is at least ten years older than his wife and she is over twenty-six. When the husband is older than the wife, and she has not attained the age of highest reproductive power, the female births will be in excess. This excess of girls born over boys is most marked when husband and wife are of the same age. Yet when the wife is the elder there is a distinct excess of male births. Dr. Kisch admits that both his own and Hofacker's statistics are not extensive enough to warrant very decided scientific conclusions. His interesting paper is published in the *Centralblatt für Gynäkologie*, January 22, 1887.

SYPHILIS AS AN ETIOLOGICAL FACTOR IN DISEASE, ESPECIALLY IN CONNECTION WITH PULMONARY LESIONS OR SYPHILITIC PHTHISIS.[1]

BY WILLIAM HENRY PORTER, M.D.,

PROFESSOR OF CLINICAL MEDICINE AND PATHOLOGY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

MR. PRESIDENT AND GENTLEMEN: Latent syphilis, both of the acquired and congenital variety, as an etiological factor in disease, has occupied my attention for a number of years past, and a large amount of clinical and pathological material has been collected, bearing not alone upon its influence on the pulmonary tissue, but upon every organ and tissue of the body. Pulmonary syphilis is best defined as a condition of the lungs in which there is a progressive thickening of the walls of the air-vesicles, preceded or accompanied by a hyaline metamorphosis of the capillary arterioles. This change is often associated with inflammatory deposits and gummy formations, which, degenerating into cheesy masses, become encapsulated or liquefy, and give rise to cavities. The first condition is best classified as a syphilitic pneumonia, the second as a syphilitic phthisis.

This subject involves many somewhat difficult and apparently contradictory problems. It is hoped that this paper and its discussion may prove of profit not only to the profession, but to humanity at large.

The chief argument is the relative importance of the syphilitic poison as an etiological factor in producing a progressive consolidation of the pulmonary tissue, which, in turn, is followed by a progressive liquefaction of the lung substance.

If the term phthisis is to be limited to tubercular lesions only, then there is no syphilitic phthisis. But if the term phthisis can be applied in its broader sense to a progressive consolidation to be followed by progressive softening with destruction of lung-tissue and the development of cavities, then this paper will clearly illustrate the frequency of syphilitic lesions of the lungs deserving the term phthisis.

The subject requires not only a study of syphilitic lesions in connection with the pulmonary organs, but also in connection with all the visceral organs, so that a pathognomonic histological structure can be clearly demonstrated by which a sharp differentiation can be made between the three lesions which heretofore have been confounded, viz., syphilitic, tubercular, and sarcomatous neoplasms.

The three may be defined as follows:

First. Syphilitic gummata are vascular growths in which the original and newly formed blood-vessels have thickened walls, due to a peculiar hyaline metamorphosis, which, in some instances gives rise to an obliteration of their lumen and the formation of surrounding concentric layers of fibrillated connective tissue and round cells, thus forming a gummy tumor. The characteristic feature of this new-formed tissue is its peripheral vascularity, the vascular walls of which are greatly thickened by this same hyaline metamorphosis. These neoplasms tend to progressively enlarge and form a distinct capsule, while the centre often degenerates and becomes caseous. At other times there is this same hyaline thickening and a permanent dilatation of the lumen of the vessels which causes an increased and irregular nutritive action of the part, which is followed by a general interstitial thickening, the contraction of which causes the frequent pockmarking of the liver.

Second. The miliary tubercles as defined at the present time, are "non-vascular nodules which do not grow beyond a certain size, and which, having attained a certain stage of development, undergo cheesy degeneration," and they now become the seat of septic infection, break down, and rapidly destroy the surrounding tissue.

Third. The sarcoma are composed of embryonic connective-tissue elements, but they do not primarily degenerate, neither do they produce a hyaline thickening of the vessels, but, on the contrary, there is often an abundant development of new and thin-walled vessels, which frequently rupture and give rise to hemorrhagic extravasations, and these may undergo retrograde changes.

From this description it will be seen that the three neoplasms may undergo a cheesy change and liquefaction. If this part only be examined the three might be confounded, but outside of the degenerating centre the sarcoma can at once be excluded.

This brings us to the chief consideration, which is to disprove the histological and clinical identity of syphilitic and tubercular lesions of the viscera, and especially in connection with the lungs or phthisis.

The author's necropsy researches have developed a firm conviction that there is a very great frequency of syphilitic lesions of the internal organs.

At the same time it is generally stated that syphilis is comparatively harmless in its nature, and is often spontaneously cured, or readily yields to treatment.

These two affirmations certainly indicate a discrepancy at some point. The first question to be considered is: How is the poison introduced into the system?

That syphilis is frequently acquired in what might be called the legitimate or venereal way no one will probably question. In fact, some have gone so far as to assert that most young men run through a course of syphilis quite as frequently as they do one of measles, and treat it in the same trivial manner.

This would make from sixty to eighty per cent. of the male population syphilitic, to say the least. If syphilis has a tendency to spontaneous cure, or is easily amenable to treatment and is not contagious in the so-called tertiary stage little harm might come from this primary indulgence. But an extended clinical observation and an abundance of pathological material strongly tends to disprove the harmless nature of the syphilitic poison and establishes a malignancy hardly equalled by any other known disease.

The following histories are frequently obtained: The husband syphilitic, the wife not, abortion follows each conception without any appreciable cause, and without any evidence of the wife being affected.

This has been explained by the poison affecting the placental structure upon the fœtal side only when derived from the father. If the poison originate from the mother's side the maternal side of the placenta only will be affected; if both father and mother be syphilitic the whole structure of the placenta will be involved.

Since noticing this assertion I have had several opportunities for confirming this fact.

[1] Read before the Section on General Medicine and Pathology of the New York Academy of Medicine, February 15, 1887.

One striking example was observed in which the mother gave birth to a child at the seventh or eighth month without any known reason for the premature delivery. Macroscopic examination of the fœtus showed a dropsy of the cord and abdominal ascites. Microscopic examination of the placenta and visceral organs gave positive evidence of a syphilitic lesion, in the shape of marked hyaline thickening of the vessels on the fœtal side of the placenta. The same condition was also well marked in the vessels of the liver, spleen, kidneys, and lungs. There was a well advanced intra-lobular cirrhosis of the liver. The vessels of the placenta and all the fœtal organs gave evidence of being waxy, both upon the application of iodine, and by the methyl-green test.

In this case there was a positive absence of any syphilitic disease in the mother, and she had been perfectly well while carrying the child up to the time of its sudden and unexpected expulsion. Such instances as these, which are frequently observed, are rather strong pathological proof in favor of direct contamination from the father without maternal poisoning.

Clinically, it may be said to originate from the father's side without contamination of the mother by frequently repeated instances such as the following: The husband contracts syphilis, supposes himself cured, marries, and his first child is strong, vigorous, and apparently free from infection. Symptoms of visceral syphilis develop, and each succeeding child shows more and more positive evidence of contamination until the fifth dies of specific marasmus a few weeks after birth. From this time on each conception is followed by an abortion without appreciable cause. During all this time no history of a primary lesion, or secondary, or tertiary symptoms can be discovered in the mother, although repeatedly sought for.

Again, the husband supposes himself cured, but his wife constantly aborts, and without any apparent cause; close examination reveals pulmonary syphilis, or syphilis of some other organ. The husband is brought well under treatment, the wife ceases to abort, and conception is followed by an apparently healthy child, the mother receiving no treatment, as no symptoms are detected in her. The husband ceases treatment, becomes broken in constitution, or dissipated, abortions follow succeeding conceptions.

In these cases treatment of the mother has no effect, but treatment of the husband invariably relieves the symptoms. Such clinical observations point strongly toward the father as the source of the poison without primary infection on the part of the mother.

The large amount of pathological and clinical proof of this nature naturally suggests the probable incurable nature of syphilis and tends to disprove the inertness of the poison in the latent periods and also proves its transmission from father to offspring.

That the surface manifestations can be caused to disappear by treatment is unquestionable, but how many specialists follow their cases through the intermediate period and on to the dead house and then work up the pathological results?

When visceral lesions develop the case naturally falls into the hands of the general practitioner or the pathologist.

To the above methods of contamination can be added all the well-known accidental chances for inoculation, which are by no means few nor far between.

This question of the disease being an acquired or an inherited vice is one of unquestionable importance. A careful study of this point, for a number of years, has led the writer to believe that pulmonary syphilis in adults is a very common disease, and that it is due to either an acquired or inherited taint, the latter being nearly, if not quite, as frequent as the former. The ground for the belief that the disease is frequently inherited is shown by the number of cases in which it appears in young persons under ten or twenty years of age, whose chastity cannot be doubted, and in whom no primary symptoms have ever appeared. In opposition to this view may be urged a primary contagion, passing unnoticed, or a direct transmission by kissing some older infected person; these are outweighed, however, by the absence of primary and secondary symptoms.

Dr. John Ferguson, of Toronto, reported a number of cases[1] where the disease occurred in young children, and where, all other treatment having failed, the symptoms yielded to an anti-syphilitic *régime*, and where the father, at a later period, inquired if his children's condition could have been influenced by his having had syphilis.

All this is proof positive of the transmission of syphilis during its latent period from a father to his offspring without the mother showing any signs of the disease. The latent period of syphilis, which lasts from ten to twenty years, during which there may or may not be exacerbations, succeeds to the active state, and usually occupies that period of life in which the larger number of children are generated, thus probably accounting for the number of cases where positive symptoms are present without any evidence of primary contagion. A positive proof of the occurrence of this disease, in the form of a pneumonia or phthisis, may be found in the fact that these complications yield quickly and favorably to anti-syphilitic treatment. The larger percentage among females, especially among the unmarried and virtuous, seems to favor inheritance. These views are those of a clinician and pathologist, and vary considerably from those advanced by syphilologists. The clinical history of a case of this character is explained by the pathological lesion, and *vice versa*. Whether it be of the acquired or inherited variety may be in doubt, but inheritance from the father's side is in keeping with the biblical prophecy of descent even to the third and fourth generations. The recognition of syphilis in causing and maintaining disease, especially when the pulmonary organs are the point of attack, would indicate that a large number were syphilitic and not tubercular in origin.

The method for determining the characteristic histological lesions of syphilis was as follows. The cases were divided into three distinct classes:

First.—Those in which there was a positive history of a primary syphilitic lesion, and in which positive symptoms of visceral involvement followed.

Second.—Those in which there was a positive absence of primary or inherited infection, and in which no symptoms could be found that would lead to the suspicion of an acquired or inherited syphilitic vice.

Third.—Those in which the history was not absolutely positive in either direction. This third group had to be thrown out, as it would raise the question of other causes for the lesions found.

In the first group all the visceral lesions, whether of the lung, liver, kidneys, brain, or spinal cord, showed a uniform appearance upon microscopic examination, viz., a marked hyaline metamorphosis of the original as well as of the newly formed vessels. Distinct neoplasms were quite common, varying in size from a millet-seed to a small orange. These gummy formations had a sticky feel, with a tendency to liquefy in the centre, and to enlarge and form a distinct and fibrillated vascular capsule. In the capsule the interfibrillated spaces were packed full of corpuscular elements, and were freely supplied with small vessels, the walls of which were thickened and distinctly hyaline. In the soft centre of the gummy neoplasm the bacilli, as described by Lustgarten, were always found.

In the second group this hyaline thickening was never present. There was no tendency on the part of the tubercular neoplasm to form a distinct capsule, and the granulating mass was non-vascular. Having reached a certain size the tendency was to break down and cause

[1] Phila. Med. News, January 17, 1885, p. 66.

further pulmonary destruction. And the bacillus tuberculosis was present.

After studying a large number of cases in this isolated way, and finding a uniform lesion in all, and its absence in all cases when there was no syphilitic taint, the firm conviction has been developed that these pathological changes are positively diagnostic of a syphilitic vice, as the cause of the diseased condition; that by these lesions we can discriminate accurately between syphilitic and tubercular lesions of the lungs. This vascular change has been attributed to other causes, such as alcohol-, tea-, coffee-drinking, etc. Some have even suggested making it a new disease. But when studied in this isolated way, all syphilitic cases showed these lesions, and in no other condition were they to be found, although carefully looked for; this makes them positive evidence of syphilis.

The changes found in the lungs are somewhat similar to those of tubercular phthisis, and caused Niemeyer to remark:[1] "It may be difficult to decide whether the lesion be of a syphilitic origin or not." The lungs may be free, but, as a rule, they are more or less bound to the chest-walls and diaphragm by newly formed connective tissue, so that the pleural space may be completely obliterated. The pleura itself may vary from one-eighth to one-half of an inch ($3\frac{125}{1000}$ to $3\frac{1}{2}$ millimetres) in thickness. The greatest thickening is at the apices. After bisecting the lung the following changes are found: The main lobes, and often the lobules, are separated by distinct bands of newly-formed fibrillated connective tissue, which is not the case in a normal lung. The bronchi, particularly the smaller ones, undergo the same change, while the bronchial glands are indurated and pigmented; the latter, however, is only a coincident lesion. There are numerous cheesy-looking masses which are recognized by a trained eye as gummy formations. Their cut surfaces have a sticky feel and a laminated capsule, which, when they have attained considerable size, is quite distinct. The smaller granules have a similar appearance, and often look as though they could be readily shelled out. These neoplasms may vary, both in size and shape, sometimes occurring as large as a hen's egg, and sometimes so small that they look like the miliary tubercle. They may occur in masses, forming cheesy-looking patches, or they may occur in single round and isolated bodies. These masses are separated by degenerated pneumonia or by an interstitial thickening of the pulmonary substance. The early stage is characterized by a diffuse interstitial thickening of the pulmonary tissue, often associated with a degenerative pneumonia peculiar to this disease. In the latter stages cavities are not infrequent, and these are also found in the apex or high in the superior lobe.

The advanced cases are the ones that are usually found on the necropsy table, while the earlier types are not infrequently associated with intercurrent disease or surgical conditions; but here the histories are very incomplete, often being passed without attracting any attention. A striking illustration of this was found in the diabetic case already published, where, in looking for a tubercular process, a typical pulmonary syphilitic lesion was found. These pathological proofs of the apex—rather than the base and anterior portion of the lung—being the point of invasion are contrary to the ideas of some previous writers, but it has been invariably so in all the cases examined by the writer, both in the post-mortem room and at the clinic. These facts also explain the physical signs which are so marked during life, and substantiate their truthfulness. Macroscopically this lesion is differentiated from the tubercular by the peculiar cheesy and granular gummy formations which have a tendency to encapsulation, and look as though they could be readily shelled out and easily separated from the surrounding pulmonary tissue.

[1] Niemeyer's Text-book of Practical Medicine, vol. ii., p. 771. New York. 1881.

The microscopic appearances are varied and numerous, and the first thing that attracts the attention is the extensive new formation of connective tissue.[1] In many places broad bands are found closely resembling tendon tissue, and intervening between these tense layers there is a universal thickening of the pulmonary tissue, which also involves the vascular walls. The yellow elastic fibres are larger, and consequently appear more abundant. In many of the cases there is little or no pigmentation found which can be traceable to inorganic substance or to blood. The absence of the first, of course, is indicative of the fact that the interstitial thickening is not due to the irritation of carbon, iron, stone, or any of the other inorganic substances, as in the case of some varieties of fibroid induration. The absence of blood pigment, on the other hand, is positive proof that it is not due to chronic congestion or impeded blood-flow. This also dispenses with the idea that the dyspnœa must be due to the stagnation of the blood.

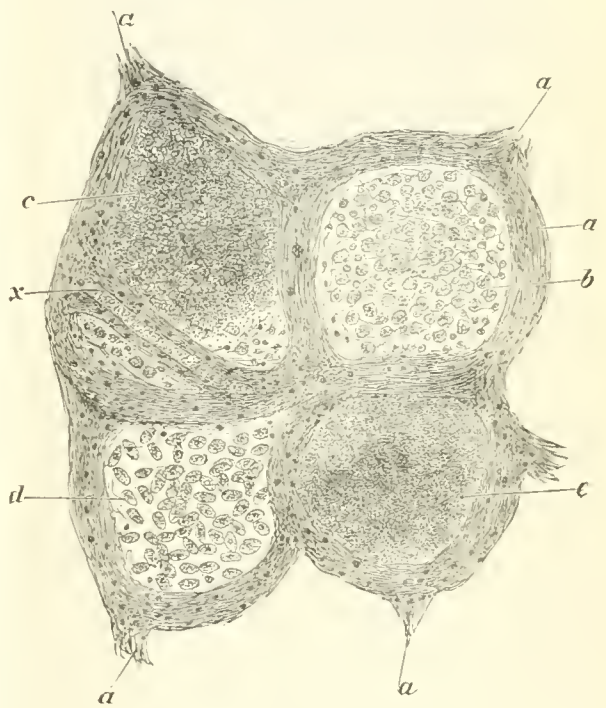

FIG. 1.—Syphilitic Pneumonia. *a*, thickened vesicular wall; *b*, an air-space showing red hepatization; *c*, an air-space showing gray hepatization; *d*, an air-space showing catarrhal desquamation of the epithelial cells; *e*, an air-space showing the degenerative pneumonia of syphilis; *x*, a blood-vessel between two thickened bands of a fibrillated vascular wall.

The thickness of the vascular walls varies from one twelve hundredth of an inch (20.833 μ) to one two hundredth (24.999 μ), but in the majority of the cases they are one eight hundredth to one six hundredth of an inch (31.250 μ to 41.666 μ) (see Fig. 1, *a*). In a number of instances the capillaries were seen in the centre of these thickened bands (Fig. 1, *x*), the walls of which were thickened independently of the vascular tissue. When the vessels were distended with blood, as in Fig. 1, *x*, the thickness of the tissue intervening between the lumen of the blood-capillary and the wall of the air-sac could be measured, and was found to be from one twelve hundredth to one four hundredth of an inch (20.833 to 62.500 μ).

This would naturally impede the free and easy interchange of gases between the two cavities, and would explain why the dyspnœa in this disease was so profound.

In addition, the connective tissue presents four characteristics microscopically:

1. Dense bands of white fibrous tissue with few corpuscular elements.

[1] A portion of this paper and the cuts first appeared in the New York Medical Journal, August 1, 1885, p. 114.

2. A less dense tissue studded with numerous small, round, inflammatory corpuscles, having an average diameter of one one hundredth of an inch (4.166 μ). At other points, this same connective tissue was thickly set with oat-shaped corpuscles one thirteen hundredth of an inch (19.230 μ) long and one eight thousandth of an inch (3.002 μ) broad.

Fig. 2.—Large Gumma, showing the outer portion and cellular infiltration the open spaces represent spots of softening.

3. The same inflammatory basement substance, interspersed with round nucleated corpuscles, one forty-five hundredth of an inch (4.166 μ) in diameter, which, taken alone, looked not unlike a round-cell sarcoma.

4. The thickened bands had a granular and degenerated appearance.

In many of the ultimate bronchi there was marked fibroid thickening, and many of the vesicular spaces were filled with an inflammatory exudation which presented a variety of appearances: 1. The air-spaces were filled with red blood-disks, leucocytes, desquamated epithelium, and fibrillated fibrin identical with that found in the second stage of a lobar pneumonia (Fig. 1, *b*). 2. Others were filled with decolorized round cells, as in gray hepatization of lobar pneumonia (Fig. 1, *c*). 3. Others were filled with large, round, distinctly nucleated epithelium cells, with a diameter varying from one fifteen hundredth to one two thousandth (Fig. 1, *d*). 4. Others contained a granular degenerating material which would not stain (Fig. 1, *e*).

The marked feature of this change was that all four conditions were irregularly intermingled as though in each air-sac it ran its course independently of all the rest, going regularly through the red and gray hepatization; at this point degeneration, rather than resolution, set in. The thickened walls prevent absorption, and the degenerating inflammatory products probably account for the copious expectoration.

This process is best classed as a degenerative pneumonia and one peculiar to syphilis. This peculiar pneumonia, accompanied by dilatation of the bronchial tubes, explains the absence of both dry and moist râles. The dilated and moist condition of the bronchi accounts for the absence of sibilant or sonorous sounds which are so common in the ordinary forms of interstitial pneumonia. This same condition of affairs accounts for the absence of the crepitant and subcrepitant râles, because the walls of the bronchi are not able to approximate each other and cause the sounds.

My opinion has always been that these râles were due to the opening and shutting of the ultimate bronchi, and a careful study of the physical signs and of a number of sections has still further convinced me that this is the way in which these sounds are produced. But I do not care to say that this is the only way in which they are produced, as they are often heard in certain stages of pleuritic inflammations, and there is no point of diagnosis between the two that is practical. The pleuritic râle, however, is very much less frequent.

It is well known that there is no tidal motion to the air beyond the third division of the bronchi. Beyond this point the air is changed by diffusion and by an anatomico-physiological law.

The trachea and bronchi are lined throughout with columnar ciliated epithelium, and the current of motion produced by these cilia is from within outward at the periphery of the lumen, while the central column of air is constantly moving downward.

It is by this action of the epithelium that the major part, if not the whole, of all inflammatory exudations into the air-sacs and smaller bronchi are brought up to the larger bronchi, where they can be influenced by the tidal air. The mass of sputum is pushed up until it reaches the under surface of the true vocal cords, where it irritates the peripheral sensory filaments of the superior laryngeal nerve, through which it is reflected back to the cough-centre, when a deep inspiration and a spasmodic or complete closure of the chink of the glottis follow. This is in turn followed by a forced inspiration with the glottis closed, during which the glottis opens, allowing a sudden escape of a large quantity of air under a very high pressure. The result of this is that the mass of sputum is driven through the rima glottidis into the larynx, mouth, or outside world, according to the force of the inspiratory act. This constitutes what is known as coughing, and is simply a dislodgement of the contents of the superior portion of the trachea. Irritation of the peripheral fibres of the pneumogastric in the pleura or bronchi will produce a dry or hacking cough. A thorough appreciation of these anatomico-physiological laws and their application to pathological conditions is absolutely essential for the selection of proper therapeutic agents.

Professor Thomas E. Satterthwaite first called my attention to the true value of the ciliated epithelium. The large gummata have a peculiar laminated, fibro-vascular, connective-tissue periphery, which tends to encapsulate

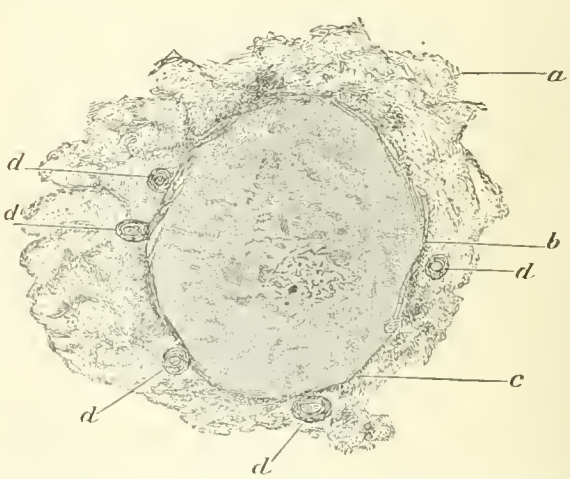

Fig. 3.—Miliary Gumma, showing cheesy centre, fibrillated connective-tissue capsule and hyaline thickening of blood-vessels. *a*, Surrounding pulmonary tissue; *b*, cheesy centre; *c*, sharply defined fibrillated connective-tissue capsule; *d*, thickened capillaries showing hyaline thickening.

and isolate their granular centres. The surrounding pulmonary substance is the seat of a peculiar fibro- and degenerative pneumonia. The capsules are highly vascular, the small vessels having thickened walls from hyaline transformation (Fig. 3, *d*); the centre often liquefies, the contents being discharged through a bronchus, leaving a smooth cavity in the pulmonary tissue. These cavities may contract and form a cicatricial "pock-

mark," or they may remain stationary for months. On the other hand, they may ulcerate and extend, so that at the necropsy we would find small smooth-walled cavities, together with larger ones with ragged walls, or sometimes with walls similar to those occurring with a tubercular phthisis.

Throughout lungs affected in this way small miliary bodies, closely resembling miliary tubercle, are abundant, but they are not opaque or transparent. These bodies I have called miliary gummata. These gummata sometimes coalesce, but at first they are round and isolated. A close study of these, in comparison with miliary tubercle, shows that there is a vast difference between the two. The periphery of the gumma somewhat resembles the adenoid tissue of miliary tubercle, but a high power distinctly shows that its periphery is composed of concentrically arranged fibrillated connective tissue in which numerous blood-vessels ramify (Fig. 3, *b*, *c*). The walls of these vessels, owing to a hyaline transformation, are invariably thickened (Fig. 3, *d*). As a rule, no giant-cells are found in the gumma.

In miliary tubercle the adenoid tissue is more delicate and less perfectly fibrillated; it is full of small round cells and often contains giant cells; the capsules are less vascular and the blood-vessels do not present the hyaline transformation.[1]

Taking the definition of Ziegler as the standard for miliary tubercle, *i.e.*, "a non-vascular nodule (*Knötchen*) which does not grow beyond a certain size, and which, having attained a certain stage of development, undergoes cheesy degeneration," miliary gumma tend to become encapsulated, miliary tubercles to soften and diffuse. Such a striking analogy between these two forms of miliary bodies naturally suggests the following queries:

1. Is not tuberculosis superinduced by syphilis?
2. In the late stages of a syphilitic lung, may we not also have miliary tuberculosis?
3. Have not miliary gumma been frequently mistaken for miliary tubercles?

The first two must be answered in the negative on account of the absence of temperature and of the Koch bacillus tuberculosis. There is, however, no good reason why a tuberculosis should not be developed on a syphilitic lesion, but the writer has not found a single instance where the post-mortem has revealed this.

Before answering the next question definitely, more data are required to prevent confounding the two.

These pathological deductions are the result of eight years' work in this direction, and a careful study of several hundred necropsies.

The rational signs in many respects resemble those of a tubercular phthisis. The patients complain of having had a heavy cold with incomplete recovery, followed by a dry, hacking cough, or one with an abundant mucopurulent expectoration. The sputum is either white and frothy, or thick, purulent, and of a greenish or yellow tinge, as in a true pulmonary tuberculosis. The copious expectoration from the very commencement is explained by the peculiar degenerative pneumonic process. Absorption is prevented by the thickening of the vesicular tissue, and all the inflammatory exudation has to be expelled through the trachea. In miliary tuberculosis there is little or no expectoration until the lung-tissue commences to break down and absorption is active. Early hemorrhages are frequent and often copious, while the dyspnœa is an early and pronounced symptom. These are accounted for by the primary diseased condition of the blood-vessels. But in true tuberculosis hemorrhages do not occur until late in the ulcerative process. Pleuritic pains are common, and there is often great weakness while the general physique remains fairly good—in fact, the emaciation is not at all in proportion to the weakness, and is nothing like that of the tubercular variety. The pains are unquestionably due to the extensive pleurisy so common in these cases. The weakness and nervous prostration without emaciation is apparently due to the inability on the part of the blood to obtain the requisite quantity of oxygen to stimulate the nervous system, and the surcharging of the blood with carbon dioxide (Co_2).

The skin is warm and moist, but there is little or no elevation of the bodily temperature. Night-sweats are frequent and distressing, and the patient complains of cephalalgia and of indefinite and wandering pains in the bones and tissues, which increase at night.

These also are explained by the want of oxygen and superabundance of CO_2. The absence of fever in syphilitic cases and its universal presence in tuberculosis is a striking and diagnostic point of differentiation. It is also clearly explained by the two lesions. In syphilitic lesions the thickening of the pulmonary substance and the marked tendency to encapsulation prevents the entrance of the effete and inflammatory products of the air-spaces getting into the lymph or vascular channels.

In tuberculosis the reverse is true. From the very onset of a miliary tubercle its inherent tendency is to break down and undergo retrograde changes. Now the effete and inflammatory products are taken up by the lymphatic and vascular channels and a true septic condition is developed with its accompanying rise in bodily heat. This abnormally high temperature is one of the earliest and the most positive symptom of tubercular lesions.

In syphilitic phthisis the stomach remains strong and with but little attention will digest well, nearly up to the last. In tuberculosis the stomach is among the first organs to rebel. Were it not for this fact many cases by forced feeding would terminate in recovery which now inevitably terminate fatally.

Dyspepsia and slight jaundice are not infrequent. The urine has a characteristic pale, limpid appearance, which, together with the sallow complexion, often leads to the suspicion of a renal lesion. The urinary examination is usually negative unless there happens to be a coincident renal lesion.

The dyspeptic symptoms and those of jaundice are usually due to similar vascular changes in the liver, and a functional derangement of that organ, and a deficient production of bile, which also accounts for the frequent constipation.

Married females abort without any apparent exciting cause further than the syphilitic taint. Their children, if born, are often plump, but soon die of marasmus. The first child is often healthy, but the subsequent children are delicate. Frequently patients complain of sore throat and of an early loss of hair.

The physical signs are peculiar and diagnostic; the respiratory act is labored and all the accessory muscles of respiration are brought into play, but there is little or no expansion of the chest. The shrinkage of the chest-wall is not apparent early, and in many instances is slight even with extensive pulmonary destruction. Early in the disease palpation reveals increased fremitus, but in the advanced cases it is diminished, owing to the small volume of air entering the lung.

Percussion gives varying degrees of dulness, which is most marked at the apex but diminishes toward the base. The percussion-note is dull and of "wooden quality," and localized areas of dulness are found. Owing to the fact that the small cavities have thin walls and contain considerable air, the dulness is not so great as would be ex-

---

[1] This form of pulmonary lesion has been quite extensively described by:

Thompson, E. Reginald: Pulmonary Syphilis, British Medical Journal, August 28, 1880.
This disease has been recognized and described from Morgagni's time to the present. A much more extended bibliography could be appended, but this is sufficient to show that the lesion has been recognized by eminent pathologists.]

pected, but, compared with a sound chest, it is decided.

Auscultation yields most positive and peculiar evidence when the rational history is taken into consideration. The inspiratory and expiratory murmurs are prolonged and harsh, especially the former, with a decided intermission between the two. Broncho-vesicular breathing is frequent at the apex.

The peculiar high-pitched and prolonged inspiratory murmur is explained by the thickened pulmonary substance and increased elastic resilience. This also accounts for the short and high-pitched expiratory murmur.

In this respect, the physical signs are just the reverse of those common to emphysema, where, owing to the loss of pulmonary substance and resilience the expiratory murmur is prolonged and high-pitched with a short and slightly increased inspiratory.

Broncho-vesicular and occasionally true amphoric breathing is heard at the apices, and the necropsy reveals the absence of any cavity. But the hardened walls of a lobule of the lung, the cavity of which communicates with a dilated bronchus, practically acts the same as a small cavity would, and explains the amphoric breathing, voice, and whisper. As a rule, crepitant and subcrepitant râles are absent, thus eliminating chronic bronchitis. It is differentiated from asthma and chronic interstitial pneumonia by the absence of the sibilant and sonorous sounds. The vocal resonance is exaggerated over the consolidated portions. The copious inflammatory exudation keeps the bronchial tubes moist and prevents the sonorous and sibilant sounds being developed. The thickened and expanded condition of the ultimate bronchioles explains the absence of the crepitant and subcrepitant râles. There appears to be no other lesion of the lungs in which the physical signs so accurately register the pathological condition.

Another very strong and pathognomonic sign is a peculiar pain and œdema of the sternum and of the tibial crests. Pressure over these regions produces a very peculiar pain, which is quite intense and accompanied by a recoil not easily forgotten when once recognized. Patients often try to avoid giving evidence of this, but as surely fail as though trying to resist the muscular reaction to the electric current. A noticeable feature is that when the sternum is excessively sensitive the tibial crests are less so, and *vice versa*. There is no other disease in which this localized tenderness and œdema of the periosteum is met with. It is never found accompanying a true miliary tuberculosis, but it is exceedingly common in connection with syphilis, and, from this absence in cases of tuberculosis, where the diagnosis was confirmed by the necropsy, and its almost universal presence in cases of syphilis, it may be regarded as pathognomonic of a specific taint. In addition to this, it is always found to disappear when the patient is under an anti-syphilitic *régime*.

The diagnosis is based upon five principal signs and symptoms:

1. The abundant expectoration without any signs of softening of the pulmonary tissue.

2. The weak and debilitated condition without marked emaciation and the good rational history of phthisis.

3. Pronounced dyspnœa without any evidence of a cardiac or pulmonary obstruction to the circulation.

4. The peculiar pain and the reaction to pressure upon the sternum and tibial crests.

5. The ready response to treatment is another element in the diagnosis.

The prognosis depends upon the early recognition and treatment. Syphilitic phthisis may run a very rapid course, but, as a rule, it is quite chronic. Dissipation hastens its progress, especially when alcoholic stimulants are used to excess.

In treating this affection, the liver should first be freely acted upon by cathartic doses of calomel or podophyllin, which in some cases should be frequently repeated. Experience has shown that the mixed treatment yielded better results than when mercury or iodide of potassium alone was used. The combination most successful is one-sixteenth of a grain of the biniodide of mercury, from five to ten grains of the iodide of ammonium, and ten to twenty grains of the iodide of potassium in a drachm of the compound tincture of gentian, three times a day after meals.

Great reliance is placed on the ammonium salt, not perhaps on account of its intrinsic action in syphilis, but from the action which it has in rendering the two others more soluble, capable of easier absorption and assimilation, and in increasing their solvent action upon these newly formed gummatous elements—in fact, its action may be compared to that of trituration on calomel.

This is, of course, only theoretical, although it was taught by the late Dr. Van Buren, and may not be in keeping with the experience of other observers, but there can be no question of its efficacy in the cases in which it has been tried. Patients have repeatedly come under observation in whom one hundred grains of the saturated solution of the iodide of potassium produced no effect, but who showed rapid improvement after a free catharsis and a maximum dose of thirty grains of the combined salts. It may be argued that recovery under the iodide is no sure proof of the existence of syphilis, as these drugs only prevent a waste of tissue and thus might retard an ordinary phthisis. It is, however, pretty generally acknowledged by writers on therapeutics that the chief potency of the potassium salts and iodide is due to their power of increasing oxidation. Upon this property our theory of their action has been based. Turkish and Russian baths are also of great service. It is quite essential to prescribe expectorants which will render the inflammatory exudation as watery and free from mucus as possible, at the same time stimulating the ciliated epithelium-cells, and thus freeing the air-passages of inflammatory products which tend to decompose, act as irritants, and interfere with the aërating space.

The best of food, air, and a total abstinence from all forms of dissipation must be insisted upon. The inherited cases are the more intractable, and will not yield to the iodide of potassium alone.

These deductions are drawn from a large amount of clinical material.

The conclusions may be summed up as follows:

1. *Etiology.*—Pulmonary lesions attributable to syphilis are very common, more so in females than in males, with the maximum number of cases occurring between thirty and forty years of age; it is as frequently, if not more frequently, inherited than acquired.

2. *Pathology.*—The lesion is most frequent at the apex and usually involves both lungs; it is a peculiar pneumonic process in the early stages, while later cavities are formed, and it becomes phthisical in the sense of progressive consolidation, followed by softening and the formation of cavities. There is a strong resemblance, but a positive difference, between syphilitic and tubercular phthisis, and a positive anatomical difference between a syphilitic and a miliary tubercle.

3. *Symptoms.*—These are peculiar and diagnostic.

4. *Diagnosis.*—This rests mainly upon the rational history and physical signs, the extreme dyspnœa, the periosteal tenderness, and the absence of an increased bodily temperature.

5. *Prognosis.*—This depends upon an early recognition of the trouble.

6. *Treatment.*—It must be anti-syphilitic to be of any avail. Many cases are unaffected by iodide of potassium alone, unless under enormous doses, but a rapid improvement follows upon the use of the biniodide of mercury, iodide of ammonium, and the iodide of potassium.

In conclusion, thanks must be extended to Dr. George R. Elliot for his pains in examining the specimens for the bacilli, to Dr. George G. Van Schaick for the drawings, and to Dr. E. B. Brunn, one of the laboratory stu-

dents, for preparing the specimens and examining for the bacilli.

In addition to the foregoing, I would like to state that, from October 1, 1884, to May 15, 1885, I made forty-two necropsies. In eleven of the cases, or 26.19 per cent., there was, in my opinion, a syphilitic condition of the lung—either gummata or cavities. Each was put to the test for the bacilli of tuberculosis, and in every instance they were found to be absent. The last three of the eleven were also put to the double test for the bacilli of tuberculosis and those of syphilis, and in all of them the latter were found in abundance, but none of the former. One case of the forty-two, or 2.35 per cent., had been diagnosticated as tuberculosis. The sputum was found to contain the bacilli of tuberculosis, and the diagnosis was confirmed by the necropsy. To the above a much larger number of necropsies can be added with a similar result.

102 East Thirty-first Street.

CASE OF WORD-BLINDNESS — CLASSIFICATION OF THE FORMS OF APHASIA.[1]

By W. H. THOMSON, M.D.,

Professor of Materia Medica, University Medical College, New York; Physician to Bellevue and Roosevelt Hospitals.

On May 1, 1884, I was called to one of my stated patients, a lady of about sixty years of age, whom I found naturally anxious about a peculiar experience which had befallen her. The previous afternoon she had taken a long ride in her carriage to Greenwood Cemetery, to visit the grave of her only son, who died three years before, of phthisis. She said that she had enjoyed the ride, and did not feel particularly fatigued by it, but on returning home began to experience a sensation of unusual weariness. She exerted herself, however, then, before going down to dinner, to write an advertisement to come out in the morning paper, for a servant-girl. She was surprised, however, to find that for some unaccountable reason she could not word the advertisement to suit her, and after tearing up some five or six such written attempts, she was obliged to ask her sister to write the notice for her. Soon afterward, while at the dinner-table, a severe pain set in at the upper portion of the left temple, which continued to increase until it obliged her to retire to her room, and not long afterward, to bed. This pain persisted through the night, but did not prevent her from having a fair amount of sleep. She rose at her customary hour in the morning, and but for the persistence of the same pain, though in less degree than on the evening before, she would not have noticed anything unusual about herself, had it not been for the arrival, soon after breakfast, of an applicant in answer to her advertisement. Upon the girl handing her some written recommendations, the lady found herself unable to make anything out of either one of them, and had to call her sister in, who then read them without difficulty. Soon another girl came in, and my patient experienced just the same difficulty in attempting to read her references. She said that her first thought was that something was wrong with her eyes, but on looking around the room and inspecting a number of small articles minutely she was satisfied that she could see and distinguish objects as well as ever. The moment, however, that she turned to the writing, while she knew that she could see the written characters as well as she could see worsted-work, yet not a single letter conveyed any idea to her mind of its character or meaning. She thereupon took up a newspaper, and at once recognized that something peculiar had happened to her, for she was totally unable to read a word in it. The separate letters could be seen, but an indescribable blur, as she thought, rendered it all indistinguishable, whereupon I was sent for to explain the difficulty.

I was much interested, of course, in the patient's story, for nothing could have been better described or expressed in words. There was neither hesitancy nor thickness in her articulation, nor confusion in diction or thought, but, on the contrary, she detailed her case with a peculiarly good choice of terms. "What is it, doctor, that makes that newspaper so illegible to me? I see that there are words there, but I am wholly unable to tell what they are," were some of her remarks. At first I directed my questions so as to avoid increasing her alarm and excitement, and in time found that she had not experienced another symptom except the above-mentioned pain and her inability to read or write. She felt no numbness or tingling, either in the face or extremities, nor any loss of power, her grasp being the same as usual in each hand, while no difference was perceptible to her between either of the lower extremities in walking. The use of the hands for sewing, buttoning, or tying, and for holding a pencil for writing, seemed as good as ever. There was no difference observable in the vision of the two eyes—no specks, nor mists, nor colored images; no marked difference in hearing on either side, nor any other symptoms referable to the ears; and there was no dizziness whatever. The face showed no distortion, either, when the patient was speaking or laughing. Examination of the radials showed them to be hard and tortuous, and the pulse was of high tension and slightly quickened. I may remark here that a brother of the patient, a few years her senior, had a slight hemiplegic attack, with aphasia, some seven years ago, from which, however, he has quite recovered.

At my first visit I was soon obliged to desist from experimenting with my patient's inability to recognize written or printed words or figures, for the plainer this strange disability became to her by my tests, the more she was inclined to become distressed by it, and to press for an explanation, so that I feared the effects of excitement upon her cerebral circulation. At my visit the next day the pain in the temple still persisted, and was uniformly described as running along a line which corresponded to the temporo-parietal suture. Some days afterward it was noticeable that she occasionally miscalled words, of which, however, she immediately corrected herself. On cautiously testing her again, I found that her word-blindness at the end of the week was complete. The largest letters, like the heading of the New York *Herald*, and figures, were as unrecognized by her, when separately pointed out, as the smallest. With the exception, however, just mentioned, her spoken language was that of a well-educated woman who had learned to express herself fluently and well.

Her recovery from this condition began in about two weeks and progressed gradually until in three months she could both read and write, especially the latter, with tolerable facility. When she began to write again, however, it was in a very small hand, but in time she quite recovered her ordinary handwriting. Since then she has shown little or no change, except a marked increase of restlessness and impatience. She now writes all her own letters, but says that whereas she used to be a good correspondent, the task of answering letters has become very irksome. Reading, however, she finds more difficult than writing, for she can read aloud only slowly; while reading to herself, she says, soon fatigues her.

A history like this goes far to support Charcot's recent classification of aphasia into sensory and motor forms, instead of the former vague and inaccurate terms of amnesic and ataxic aphasia, because it shows a derangement of speech complete in itself and yet limited to the impressions of one special sense alone, viz., that of sight. Words reached the brain through the ear as well as ever, and therefore conversation was so perfect that the patient only accidentally learned that all language on paper was for her impossible. The eye could not "speak" a word to the consciousness. To this sensory defect of

[1] Paper read before the Neurological Section of the New York Academy of Medicine.

speech the term word-blindness has been given. But quite parallel to this case of sight aphasia we may have a person whose brain can see words perfectly but cannot hear words, although it can hear everything else. Examples of word-deafness, indeed, are even more curious than examples of word-blindness. Thus Broadbent relates the case of an intelligent and well-educated patient who became speechless from a syphilitic neurosis, but who evidently could read his newspaper, as he showed by going once to the nurse, in much excitement, to point out the announcement in the paper of the failure of a firm with which he had business relations. When asked to read aloud, he complied readily, but the result was gibberish, which his defect, however, prevented him altogether from perceiving. A sentence which read, "The Odessa line is again working properly," he read, "The assoil lens a puft puff miss corres povety," and so on, reading seriously and steadily, quite unconscious of the absurdity of his utterances. When trying, also, to copy a sentence, as he wrote each letter, he *named* aloud the letters always wrongly, although he *wrote* them correctly. In this case, therefore, the sounds which the brain had been taught to *hear* as words no more reached the consciousness as words than the written forms which the brain had been taught to *see* as words were perceived as such by my patient. That the defect in either case is something very different from amnesia or forgetfulness is proved by the fact that the *mind* has not forgotten a single word, only its equivalent "eye" or "ear" symbol, as the case may be. Why, therefore, the foreign language in which the patient with word-deafness talks to himself is not recognized by him as such is because the eye being still in perfect word use, and hence the meaning of what he reads being as intelligible as ever, he does not suspect that the ear is giving him no word-sound at all, so that he can neither articulate words to others nor himself recognize that the noises which he makes are not words. For it must be remembered that neither sounds nor forms make words; this is done wholly by the consciousness, and it does this out of sensory registrations in themselves specifically unlike. Thus, the sound of the word "man" is as different from the written word "man" as a strain of music differs from a painting. Moreover, it is quite probable that modern progress has enlisted another sensory, and correspondingly distinct registry of words in brain cells related to the sense of touch in the case of the blind who are taught to read with their fingers, and therefore we can conceive of a sightless aphasic who, by the appropriate lesion in his brain, might as suddenly lose his "touch" words as "sight" words are lost in word-blindness and "ear" words in word-deafness.

Such instances establish, at any rate, the fact of purely sensory aphasia, or derangement of speech from damage to groups of sensory cells which have been made to store up each their own kind of impressions, which to the consciousness represent words. Unfortunately, such brain-impressions cannot be made hereditary, like the sounds which animals utter, because it was none of the original business of those cells to have anything to do with speech, and their final perfection of training in word-registration is the sole effect of education, quite as special in its way as that of the gustatory sense in the German wine-tasters who with a mere sip will tell at once the vintage year of more than a dozen samples of hock. However, the recent progress of the pathological anatomy of aphasia, in spite of many difficulties, enables us now to locate pretty definitely the seat of word-blindness to be in lesions of the angular gyrus and its adjacent parts, or the visual centre, while in word-deafness we may look for signs of injury about the acoustic centre in the first and second temporo-sphenoidal convolutions, or in the track of their respective conducting nerve-fibres. It is an interesting observation which goes to prove that nerve-cells are taught word-language only by special effort or training, that facts of disease seem to indicate that articulate speech is a development from gesture speech, for the only explanation why aphasia is so generally associated with paralysis of the right, and not of the left, side of the body, is that the use of the right hand first for expressive gesture led to the employment of the contiguous motor centres in the left brain for the tongue, lower jaw, and face to utter sounds along with the movements of facial expression. That the corresponding centres of the right brain, however, can be taught speech equally well with those of the left brain, is proved by instances of complete loss of speech with paralysis of the left side of the body in left-handed persons, a perfect example of which I had not long ago in a left-handed patient of mine.

But clinical experience shows another and a much more common form of speech derangement whose characters cannot be referred to the sensory or receptive functions of the mind. One of the oftenest-occurring kinds of aphasia is where the patient loses all power to address others, for he can find no words come to his lips if he attempt to talk, or to his hand if he attempt to write, and even if he try to gesticulate he frequently makes the wrong movement with head or hand to what he intended. Yet, though he cannot address others, he still can be addressed, for he can understand all talk *to* him, and can himself read either print or writing, sometimes being even able to recognize the handwriting. In him, therefore, it is plain that the sensory mechanism of speech is intact, for he can both hear words and see words—but he cannot *use* words. The distinctive feature of this form of aphasia, therefore, is inability to work the mechanism of expression. A few words may be left to the patient's tongue, but they are mere sounds, and are often used over and over again without sense, like Broca's patient, who said *tan tan* to every question for twenty-one years.

This loss of power of expression is now properly termed motor aphasia, as it corresponds essentially to the motor or "out-going" element of nerve-function, just as sensory aphasia corresponds to the receptive, or in-coming, element. In distinction, therefore, from the receiving of impressions, as in listening or in reading, all mental acts connected with language which demand the putting forth of effort may be properly classed as belonging to the motor department of speech, for they show that the mind has first received the materials or sensory symbols of ideas, and constructing ideas therefrom, has then sent them forth. All *speaking*, therefore, whether by word of mouth or by handwriting, or by a wink of the eye, is a motor act which has as distinct a motor nervous mechanism as winking itself, which can be done only by a motor nerve acting on the palpebral muscles. It is moreover familiar to everyone that we receive thoughts by ear or by eye much more readily and quickly than we can express them in turn to others, which shows that the two processes are distinct, and not interchangeable. So that out of any five persons receiving equally clearly just the same idea there would be found a great variety of faculty or power for expressing it afterward, while disease shows that one process may be destroyed without the other being affected.

But between these two kinds of aphasia, namely, word-deafness and word-blindness on the one hand, and paralysis of expression on the other, we have a puzzling series of mixed cases with most varying degrees of the symptoms of each of these two kinds. Thus, cases are recorded (Trousseau) in which the patients could not utter a word, but could write as well as ever. Here there was motor aphasia, but limited to only one mechanism of out-going speech, *i.e.*, the mouth, without affecting expression by the hand. It is curious that motor speech is sometimes intact in word-blindness, even when the expression is by writing, for cases are recorded (Broadbent) of patients writing correctly while they could not read anything—not only printed characters, but what they themselves had just written. This fact can be explained

only by admitting that when one learns to write, which is long after he has learned to speak, he teaches the art of writing to new nerve-cells which are different from those which ordinarily register word-forms, and which, therefore, may remain in working order when the visual cells are paralyzed.

In addition to these forms of speech derangement, we have still others, the most important of which is *paraphasia*, in which the patients are constantly using wrong words, and others, again, in which entire classes of words, most commonly nouns, are lost. Some of these cases I think, can be best explained by admitting a third element in speech, which would correspond to the ganglionic centre of a simple nerve-arc. For just as we have derangements of sense registration of words, or sensory aphasia, and derangements of expression by words, or motor aphasia, so we may have derangements of recognition of words by the consciousness, or centric aphasia. Parrot talk, for instance, has but little of the centric element in it. A higher example of the same sort of words without thought is found in our committing to memory a passage just for the sake of its words, although we have its meaning perfectly in our minds. The degree, in fact, of our recognition of the words which we use is so various on different occasions, that we speak of not realizing sometimes what we have been saying. We can therefore conceive of the mental recognition of words depending upon the vividness of the impression with which they have been registered in the nerve-cells or centres nearest related to the consciousness, and which impressions, in turn, may fade in disease until the consciousness cannot perceive them at all, and hence cannot use them. Meanwhile the lower sensory mechanism still retains them, for if you ask these patients to repeat the words after you, or to copy by dictation, they may be able to do so quite readily. Hence, any indistinctness of the impressions on these higher speech-centres would result in the consciousness often mistaking them, and thus producing paraphasia.

Losses of nouns, on the other hand, occur like Bergmann's case, who had to use a paraphrase for every noun, as for scissors, "that with which one cuts," or for window, "that through which one sees." This interesting form of aphasia plainly suggests that language is acquired, so to speak, in successive layers of specific impressions, those classes which on account of the constitution of the mind are registered first remaining the longest, and those which are registered last fading away the soonest. For there is this fundamental difference between verbs and nouns, that verbs are subjective while nouns are objective. Now, subjective words are associated in the consciousness, from the first, with some inner experience, and hence will be much more deeply impressed than those which are rather associated with external or objective impressions. Thus, the consciousness that I see, I hear, or I feel, not only long precedes the recognition of what *thing* I see, or hear, or feel, but the event itself is much more deeply impressed as an idea than the object of the event, which often does not till long afterward receive a name, and thus become a noun. Even yet, in English, the sense of touch is but imperfectly supplied with its distinctive nouns, for while we can say, I see a blaze, or I hear thunder, instead of, I see the appearance of a blaze, or I hear the sound of thunder, we cannot say I feel a fire, or I feel an ice, but are obliged to use some paraphrase, just as Bergmann's patient had to paraphrase every objective term. Nouns, or the names of things, therefore, are more external to the consciousness than verbs, which, instead of being the names of things, are the terms which denote events in experience, *i.e.*, either perceptions or actions. Nouns, therefore, in proportion to their objectivity, partake of the nature of pure names, like proper names, which, as everyone knows, are the last words to be learned and the first to go. That words, indeed, are not learned haphazard in human speech, however, they may be by parrots, but rather by classes, in obedience to mental laws (and hence, can be lost by classes), is confirmed by Ogle's observation that grammatical form is always observed by aphasics in the few words that remain to them—substantives are used in the place of substantives, verbs for verbs, numerals for numerals. Thus, a patient of Broca employed *trois* to express any number, but corrected what he said by holding out the proper number of fingers at the same time. A patient of Dr. Broadbent also possessed only one name for a locality, namely, Burlington, where she had lived as a child, and she used this when she wished to name any place whatever. Kussmaul, it is true, speaks of an Agrammatic aphasia in which the parts of speech are confused, but his instances of the kind belong rather to the category of brain lesions which destroy speech by first destroying thought itself, and in which the patients can hardly be termed aphasic, any more than we can so call speechless, though not wordless, idiots.

Cases of partial, and yet specific, aphasia, like that of my patient here detailed, are interesting on account of the light which they throw upon the cerebral mechanism of speech itself. It is doubtful if the labors of generations of metaphysicians could show us how the mind acquires words, or thinks in them, with anything approaching the demonstration that is afforded by some examples of derangements of speech by disease. Thus, it would scarcely have been surmised by any train of *à priori* reasoning that the faculty of speech was divisible into so many distinct elements or factors as the histories of some aphasics prove. One would as little expect an artist suddenly to lose all power of representing a man while he could still paint a horse as well as ever, as to find a person who wakes some morning with all his nouns gone, or else of a scholar who in an hour becomes as illiterate as a savage who has never seen a written or printed word. But the literature of aphasia abounds with cases which read not unlike careful experiments made for the purpose of analyzing the different mental elements of language separately, so as to enable us to reconstruct the whole with that kind of certainty which only experimental tests can afford.

A CONTRIBUTION TO THE STUDY OF DISEASES OF THE UVULA.

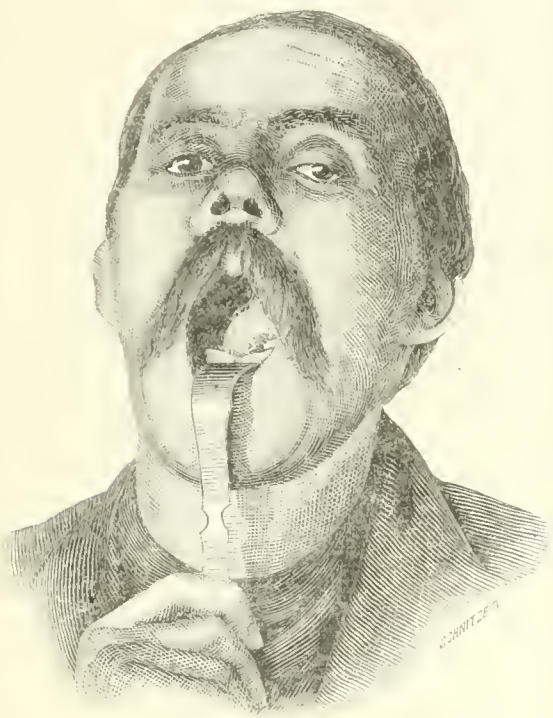
By WENDELL C. PHILLIPS, M.D.,
NEW YORK.

Primary disease of the uvula is rarely seen. Most diseased conditions of the organ are either due to extension of disease of the surrounding tissues, or are local manifestations of constitutional disease. For instance, acute inflammation of the uvula, or uvulitis, is usually due to extension of general inflammation of the pharynx. Œdema is never primary. Chronic elongation is the result of chronic pharyngitis. Lupus does not primarily affect the uvula. Papillomas are occasionally seen, but are usually dependent upon syphilis or tuberculosis. Anæsthesia, hyperæsthesia, spasm, and paralysis are always due to external causes. These, in conjunction with certain congenital conditions occasionally seen, complete the list of diseases in which the uvula may be involved. And it may readily be seen how exempt this organ is from the primary manifestation of disease. A case of angioma primarily developing in the uvula has recently come under my notice, and, after patient research, I am led to believe that no similar cases have previously been reported.

John S——, aged thirty-nine, married, plasterer, was sent to the Throat Department of the Manhattan Eye and Ear Hospital by Dr. George F. Carey, July 31, 1885. For two months he had experienced some difficulty in swallowing, and at that time was taking only very soft or liquid food. He had been gradually losing flesh and strength, and his general appearance was haggard and anæmic. He had a chancre two years ago, and one year ago had an operation for urethral stricture.

The uvula was greatly enlarged in every direction, but more especially in length, it being two inches long. The diameter was five-eighths of an inch, terminating in a bulbous mass considerably larger. When in repose this mass hung well down behind the base of the tongue, but caused him very little unpleasantness, except when eating. With slight effort he could force the tumor forward upon the tongue. Numerous small, dark-blue, apparently venous dilatations were visible over the entire surface of the growth. The man was positive that the condition had not existed more than two months. Supposing the disease to be of specific origin, he was given the mixed treatment with tonics.

About this time the tumor was photographed by Dr. George H. Fox. Owing to the great length of the growth and the irritability of the patient's throat it was found impossible to get a good photograph of the entire mass.



The illustration above shows the base of the tumor fairly well and slightly tilted forward upon the tongue. The view given is really from below upward.

During July and August the specific treatment was faithfully followed. His general health improved slightly, but the tumor gradually enlarged. The same conditions also began to appear on the surface of the left velum.

November 6th.—Still increasing.

December 1st.—Specific treatment was abandoned. The tumor was still increasing. During January, February, and March, 1886, he was seen at short intervals, and the growth was treated locally. It was now two and one-half inches in length and interfered greatly with deglutition. It was evident he could not live much longer in this condition, as he was failing rapidly. Consequently an operation was decided upon.

May 4th.—The entire growth was removed with the galvano-cautery. The hemorrhage was very slight. He made a good recovery, and was discharged from the hospital, May 10th.

July 15th.—Returned. He had gained twenty pounds of flesh, and had steadily improved.

October 1st.—He was working steadily at his trade, and gave no evidence of a return of the disease.

The tumor was taken to Dr. T. Mitchell Prudden, who made the microscopical examination. He made the diagnosis of *cavernous angioma* of the *uvula*. The following is his report, viz.:

"*Tumor of the uvula, from Dr. W. C. Phillips.*—The irregularly pear-shaped tumor is roughly nodular on the surface and considerably shrunken by the preservative fluid. The tumor-mass consists for the most part of a congeries of larger and smaller irregular-shaped cavities lined with endothelium and filled with blood. Between these blood-cavities are bands of connective tissue, dense and firm in texture. The muscle-fibres of the uvula are crowded apart by the new-formed blood-cavities, and lie scattered singly and in groups in the connective-tissue bands or partitions. The mucous glands are crowded out of place and moderately hypertrophied. While most of the cavities are filled with simple, clotted blood, some of them are partially, and in a few cases nearly, completely filled with parietal thrombi, which have only central lemma filled with blood. The whole is covered by the normal mucous membrane of the part. The anatomical diagnosis is, accordingly, *cavernous angioma* of the *uvula*. T. Mitchell Prudden."

A CASE OF DEFORMITY OF THE RIGHT HAND, IMPROVED BY PLASTIC OPERATIONS.

By GEORGE WACKERHAGEN, M.D.,
BROOKLYN, N. Y.

On February 14, 1884, Carrie M——, aged fifteen years, a resident of Dutchess County, N. Y., working at her occupation of laundress, caught the middle finger of her right hand in the revolving cylinders of a steam mangle. Before the machine could be reversed the whole hand had been drawn between the rollers and exposed for several minutes, not alone to the great pressure and lacerating force of her voluntary resistance, but also to the boiling water and steam.

Surgical aid was at once obtained and such attention given the case as was demanded. In the summer of 1885, about eighteen months subsequent to the accident, she came, by consultation with Dr. Thomas J. Barton under the notice of the writer. The hand being entirely helpless, a series of operations was designed to produce a more useful member.

Fig. 1.

Fig. 1 gives some idea of the relative position of the fingers, but the amount of cicatrix and the firmness with which all parts of the palmar surface were agglutinated cannot be represented. The lacerating forces and scalding had stripped the soft tissues of the palm "to the bone." The healing by granulation and cicatricial contraction, unopposed by a similar force on the dorsum, had flexed the fingers and coalesced the whole front of the hand, including the thumb, in one firm cicatrix. The deformity was further increased by a fracture of the fourth and fifth metacarpals, with forward angular displacement of the fragments, and dislocations at both articulations of the first phalanx of the fifth row.

Under ether anæsthesia **V**-shaped incisions were made in the scar opposite the index, middle, and ring-fingers, and extension nearly to a right angle made possible. The little finger being so hopelessly disabled, its phalanges were dissected out from the scar, and whatever sound in-

tegument could be obtained from it utilized to improve the condition of its fellows.

Suitable dressings being applied, careful instructions were given concerning the manipulations of which the post-operative treatment should consist in such a case. These directions were but poorly executed, as was learned at the next visit on December 1, 1885, when the condition was essentially unchanged. (It will be noted that the patient and operator lived widely apart.) At this time the patient being again anæsthetized, a second operation was done. The first step consisted in thoroughly removing all scar-tissue. The viciously united metacarpals, with the useless ring-finger, were dissected away without loss of the normal integument of the dorsum, which was drawn around to cover the palmar surface of the first and second metacarpals. The cicatricial tissue was now entirely replaced by normal integument. Instruction concerning passive movement of the two remaining fingers being repeated, the patient was not seen again until March, 1886, when marked improvement was noted. Both active and passive movements were greatly facilitated, and the nutrition of the fingers was much better, the circulation being re-established and maintained to a natural degree.

Most of the disability was now caused by the immobility of the thumb, consequent upon its adhesion to the side of the index-finger. To correct this, a skin-flap was formed from the adjacent portion of the back of the hand and index-finger (Fig. 2), which was brought forward to form a palmar surface and ball of the thumb.

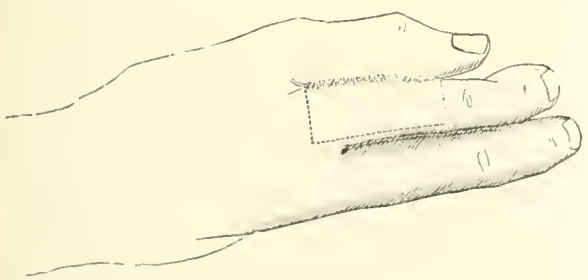


Fig. 2.

The deficiency thus produced was supplied by completely covering the freshly cut surface with small grafts from the arm. Every one of these united.

The hand resulting from this series of dissections and patchings is a very useful member (Fig. 3), and with use

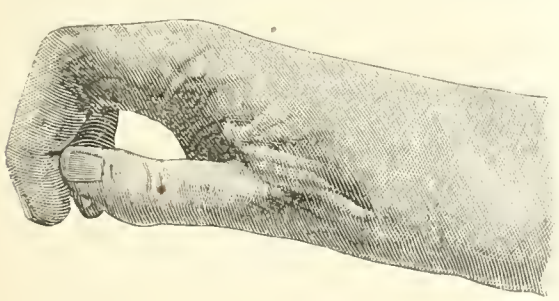

Fig. 3.

is becoming adept at prehension and ordinary manual functions, there being considerable motion and strength in both fingers and the thumb.

A Simple Test for Butter.—There is a qualitative test for butter so simple that any housewife can put it into successful practice. A clean piece of white paper is smeared with a little of the suspected butter. The paper is then rolled up and set on fire. If the butter is pure the smell of the burning paper is rather pleasant, but the odor is distinctly tallowy if the butter is made up wholly or in part of animal fat.—*Scientific American.*

Clinical Department.

SOME THOUGHTS ON TYPHOID FEVER AND ITS TREATMENT.

Dr. B. F. Ludlum, of Marion, Ind., writes that his interest was excited by a statement made by Dr. Baruch in an article in The Medical Record concerning the mortality in this disease. The author said: "If we appreciate the enormous mortality of typhoid fever, as gathered from the reports of our city Board of Health, we must acknowledge that this disease is a scourge in New York City." He then gives figures showing an average mortality during the past ten years of 41.28 per cent., and during the autumn of 1886 of 34.68 per cent. Dr. Ludlum continues: "These certainly are alarming figures of fatality, and remind me of the declaration I heard an old man make, soon after I entered civil practice, that 'We think here when the physician pronounces his case typhoid fever the patient had better make his will.'

"I was congratulating the medical profession that in its advances it had almost blown away the wonderful dread of typhoid fever and placed it nearly alongside of rheumatism as regards its mortality. After treating fifty or sixty cases in Warren County, O., without any proving fatal, I was accustomed to tell the patient and friends that we expected our typhoid fever cases to get well, and it always turned out so, until after I had treated one hundred cases.

"On my first day of practice I was introduced to a case of typhoid fever. Having a terrible dread of this disease, I threw all my energy into the study of the case. In all my reading and conversation with other physicians, the burden of the matter was the uncontrollable diarrhœa and the lesion of the bowels. Reasoning from these as facts, I determined to direct all my efforts to allaying the excitability of the stomach and bowels by not only not giving cathartics or emetics but by using every means of restraint that I could command to prevent nausea or diarrhœa. I usually found the Dover's powder or some other opiate and subnitrate of bismuth quite efficient, yet when these did not bring the desired result I took such other medicines as met the indication to allay irritability of stomach and bowels. Ordinarily I gave turpentine in emulsion, so that from twelve to twenty drops of the drug would be taken in twenty-four hours in four to six doses, or, if the turpentine was not agreeable, I gave muriatic acid mixture in about the same dose, combined with five or six drops of the nitric ether. For tympanitic distention of the colon I used embrocations of lard and oil of turpentine over the abdomen, also the hop poultice, steamed over boiling water or vinegar.

"My observation from first to last in regard to this fever has been that the general tendency of the disease is of a depressing nature, and therefore, if any medicine that depresses the system is given, it lessens the vital forces, weakens the nervous system, and is one of the means of opening the excretory ducts of the alimentary canal to flood away the life by irritation and depression, and this at the very time when every atom of strength and nerve-force and every available drop of blood is called for to carry the patient through the weeks of time when there is but little appropriation of aliment to the weak organs to make blood or recruit the failing powers of life.

"I never could find time to give attention to the matter of antipyretics, and had no inclination to until something was advocated that gave better results than I was obtaining by my common method of treating this fever. It was a more ancient idea that fever was the disease, and was the matter in hand to be treated, while there has been a later and not less authoritative doctrine that fever is only a symptom of disease.

"The older doctors bled, gave tart. antimony, veratrum, etc., to reduce the pulse and fever, and also produced ptyalism for the same purpose, and, as they expressed it, to break up the fever; and, when the patient had constitution enough to stand the treatment, they usually did so. Seeing that homœopathists had better results by almost no treatment, as they thought, gradually they abandoned the heroic plan and went to the other extreme, viz., the expectant, which really brought better results. A plan of mild treatment, one which will permit small doses of non-irritant antiseptics and non-irritant hæmostatics, and small doses of tonics that will strengthen and tone up the system, has proved to be of greater value. Milk is probably the best aliment for most cases. I am positive that for safety and effectiveness as an antipyretic there is nothing equal to moderate draughts of cold water, given frequently. It will invigorate every time, as well as reduce fever. It is a thin beverage, but it will keep a man living a long time. Another thing of first importance is, have good nursing."

COCAINE IN ACUTE GASTRITIS.

Dr. J. Emmet O'Brien, of Scranton, Pa., relates the case of a young girl who, after an unsuccessful attempt at suicide by laudanum, mixed a box of "Rough on Rats" in water, and drank an unknown quantity of it at intervals during a half hour. When first seen she was in frightful agony, and the diagnosis of arsenic poisoning being quickly made, the stomach was emptied by ipecac and sulphate of zinc, and large quantities of dialyzed iron and lime-water were given. Dr. O'Brien gave two grains of morphine hypodermatically in divided doses during the night, and kept the woman anæsthetized by means of chloroform and ether for twelve hours. When conscious, the patient would take nothing unless assured that it was poison. Whenever the anæsthetic was withdrawn the patient would try to dash her brains out, and tore at her abdomen, raving about her stomach. Three persons could with difficulty hold her when not profoundly under the influence of ether. Twelve hours after the poison had been taken the girl was still in terrible agony, and showed signs of collapse. On the suggestion of Dr. Gunster over half an ounce of a four per cent. solution of cocaine hydrochlorate (about ten grains of the drug) was then administered, the supposition being that all the arsenic had been vomited or neutralized, and that gastritis was now the condition calling most loudly for relief. In a few moments the patient ceased to complain of her stomach. The mania subsided, and the patient became controllable, so that it was possible to discontinue the anæsthetic. The pulse, which had been failing, grew stronger, and the woman was soon able to walk with assistance. The mania and hallucinations continued in mild form for some hours. The patient was removed to the Lackawanna Hospital, where brandy and digitalis were given, and she recovered completely. According to the analysis of Mr. Lorenz, an apothecary of Scranton, "Rough on Rats" contains sixty-five per cent. of arsenic. Another girl, who afterward took some of the same preparation, died within a few hours. The treatment in this case was not known.

THE TREATMENT OF CONSTIPATION.

Dr. George T. McCoy, of Columbus, Ind., contributes the following: "Having read the article on 'Constipation' in The Record of March 5th, I wish to offer a suggestion. Instead of an 'enema of olive-oil and water' or the 'compound aloin pill,' use suppositories of aloin, gr. $\frac{2}{3}$; ext. belladonna, gr. $\frac{1}{4}$; strychnia, gr. $\frac{1}{30}$; butter of cacao, q. s. About two years ago I commenced treatment of simple constipation by the use of suppositories, and have no hesitation in saying that it has given more satisfaction both to patient and physician than any other method of treatment. Of course, this includes 'obedience to physiological law.' Many cases of constipation in this latitude are simply local diseases —'paralysis from over-distention'—and when complicated by piles the suppositories are of great benefit.

"I use the same treatment in many cases of constipation among infants, using nux vomica instead of strychnia, and making strength of suppositories to agree with age, etc. A suppository of the strength of the above will seldom fail to produce a free evacuation, devoid of any unpleasantness, after which strength and frequency should be gradually lessened. Through the courtesy of Parke, Davis & Co. in preparing samples, I have been able, in several cases, to relieve this most distressing ailment even when it had existed for 'half a lifetime.'"

Progress of Medical Science.

Salicylate of Ammonium in Typhoid Fever and other Febrile Diseases.—Dr. J. R. Barnett, of Wisconsin (*Journal of the American Medical Association*), impressed with the idea of the inadequacy of quinine in typhoid and remittent fevers, advocates the use of salicylate of ammonium, which he regards as a safe and efficient antipyretic. From a rather limited number of observations he believes that the following conclusions may be provisionally accepted: Salicylate of ammonium is to be ranked among the most efficient of the antipyretics. As an antipyretic in all fevers characterized by extreme adynamia it ranks among the safest, owing to its ammonium base. It is stimulant as well as antipyretic, and thus of itself fulfils indications otherwise only met by a combination of remedies. It is an agent of wide germicidal powers, being promptly efficient in affections of great etiological and pathological differences, each confessedly arising from its own proper specific infecting micro-organism. As a remedial agent in typhoid and remittent fevers it is unsurpassed, aborting them at the outset, under favorable conditions, and greatly mitigating their severity and danger under circumstances less favorable. It is entitled to confidence in the treatment of pulmonary inflammations, either idiopathic or septic, and probably eliminates the dangerous factor, embolism, with greater certainty than any other curative agent. It is the most efficient known remedy in puerperal septicæmia, and probably also in most septic inflammations of non-puerperal origin. It is worthy of a trial in non-tubercular cerebral meningitis, as it gives some promise of relief in an affection which has hitherto resisted, if not resented, all modes of medical treatment.

Treatment of Ciliary Blepharitis.—Dr. Gorecki divides the treatment of this affection into four parts: First, the treatment of the cause; secondly, that of the local symptoms; thirdly, that of the general constitution; and, lastly, hygienic treatment (*Recueil d'Ophthalmologie*). In young and adult men the cause of blepharitis is, in many instances, defective discharge of their functions by the lachrymal passages. One eye weeps, the lids become congested, the bases of the cilia become red, an abnormal secretion forms along the edges. In such cases the permeability of the lachrymal passages must be restored. In other cases some anomaly of refraction or of accommodation is the exciting cause, and the effects become particularly well marked when the patient is much engaged in writing or in reading. In such cases appropriate glasses must be prescribed. The local treatment should never be irritating. In most instances topical applications should be made by the surgeon himself. As a rule, ointments are not well borne at the outset. They should only be applied when the eyelids are not irritable, and their use should be suspended as soon as they seem to cause any irritation.

When ulcers or an eczematous condition is present, which is of not infrequent occurrence in children, the crusts and scales should be removed by a hot starch poultice. The cilia should then be thoroughly cleansed, especially at their bases, with warm water containing four or five per cent. of boric acid, or one-half per cent. of carbolic acid, or use may be made of an infusion of chamomile; and, lastly, the surgeon should himself touch the base of the ulcers with the point of a pencil dipped in a solution of nitrate of silver containing two or three per cent. of that salt, and the same may be applied to the roots of the cilia, water being subsequently applied freely to wash away any excess of caustic. This last proceeding should be adopted every, or every other, day, according to the condition of the lids. In the case of dry blepharitis, with branny scales at the base of the cilia, with neither scabs nor ulcers, hot, slightly antiseptic fomentations should be applied. Pomades composed of mercury nitrate, or with acetate of lead, are given in all books, but are of little service. A solution of perchloride of mercury, one part in two thousand of water, and twenty parts of glycerine, may be applied; and calomel may be dusted over the surface of the edges of the lids. The general treatment may consist in the administration of small doses of calomel internally in eczematous infants. Arsenic is very efficacious in adults. Salt-water and sulphuretted-water baths should be prescribed with care, and only after due consideration. The general hygienic treatment is of great importance. The patient should live in pure air, should avoid a sandy or dusty soil, should smoke only in the open air, and should take little or no alcohol. Attention should be paid to the bowels; and vegetable tonics may be taken.

Syphiloma of the Heart.—At a late meeting of the London Pathological Society Dr. W. Pasteur showed a specimen of syphiloma of heart from a woman aged thirty, who was taken to Middlesex Hospital *in articulo mortis*. She was probably a prostitute. None of the ordinary signs of syphilis were visible except in the heart. The liver had a peculiar marbled appearance. There was some recent lymph on the surface of the left ventricle, which was hypertrophied and dilated. Grayish opaque patches of varying size and distribution were seen in the wall of the ventricle and septum. At least one-half of the ventricle was diseased. The right ventricle was less diseased. The patches were ill-defined and translucent at the edges. There were milky-looking patches on the endocardium. Microscopical sections showed infiltration of corpuscular growth, which was very vascular at the margin; the nuclei were spherical and distended. In some of the vessels of the heart doubtful evidences of peri-arteritis were to be seen, and possibly also of endocarditis. The liver showed numerous accumulations of small round cells, like that met with in some forms of interstitial hepatitis of congenital syphilis.—*The Lancet*, January 1, 1887.

Diagnosis and Treatment of Gonorrhœal Cystitis.—The following are the conclusions of an article on this subject by Dr. Ernest Desnos (*Bulletin Général de Thérapeutique*, November 15, 1886): 1. Gonorrhœal cystitis has its seat in the cervical portion of the bladder; it always exists together with a deep urethritis, but the latter alone cannot give rise to all the symptoms of cystitis. 2. In the commencing stage of gonorrhœa there may be a frequent desire to urinate, but the short duration of this symptom and the absence of other characteristic signs suffice to exclude a diagnosis of inflammation of the bladder. 3. In chronic cases the differential diagnosis between gonorrhœal and tubercular cystitis is sometimes impossible, especially when the latter supervenes upon an old gonorrhœal inflammation. 4. A certain number of cases, called cystalgia or neuralgia of the neck of the bladder, are nothing else than incompletely cured cases of gonorrhœal cystitis; but at times, even after a complete cure, a certain painful sensation persists for a very long period. 5. The treatment o acute cystitis by means of emollients is rarely successful and merely prolongs the disease; even in the acute stage, applications of nitrate of silver should be made to the neck of the bladder; a smart reaction is manifested the first time, but improvement rapidly follows. 6. In chronic cases, washing out the bladder is of little use, and may even cause an acute exacerbation; in such cases general treatment is a good adjuvant to the indispensable local treatment. 7. This local treatment should consist in direct instillations of certain remedies to the neck of the bladder. 8. Sublimate solution, in the strength of 1 to 250 or 1 to 500, causes severe and prolonged pain, and its effects are slower than those of nitrate of silver. 9. Iodoform dissolved in oil or suspended in glycerine is not painful, but its effects, although in the main satisfactory, are slow and uncertain. 10. Hydrochlorate of cocaine quiets the pain only for a very short period; but when applied to the neck of the bladder some minutes before the instillation of a caustic, it causes a very sensible diminution of the pain of the latter. 11. From all points of view, however, nitrate of silver possesses an incontestable superiority over all other therapeutic agents.

Intermittent Albuminuria.—Dr. Mareau relates, in the *Revue de Médecine* for October, 1886, a case of an apparently healthy boy who had intermittent albuminuria. The child had never been ill until he reached the age of eight, after which time he had measles and typhoid fever. The author raises the question, without solving it, whether there is actually such a thing as physiological albuminuria, or whether the affection should be regarded as the result of a pathological process, however slight. He concludes his study of the case with the following considerations: 1. There exist forms of albuminuria, of unknown nature, which are compatible with a state of health. 2. The chief characteristics of these forms are that they are intermittent or transitory, and that the amount of albumen is never or very rarely large. 3. The intermittent albuminuria, in the case of the boy in question, was more marked after meals than at any other time of the day. 4. The influence of food upon the albuminuria was especially accentuated by the evident traces of albumen. 5. The slight trace of albumen which was observed in the case of the boy, in the urine passed the first thing in the morning, was without doubt attributable to the effects of the evening meal, for he urinated but once in the evening on retiring, and then not again until morning. 6. The attack of measles from which he suffered had no effect in increasing or diminishing the amount of albumen excreted. When, by reason of the fever, the boy could not eat as usual, the albuminuria was most noticeable in the early morning; but during convalescence, when he began to take his ordinary meals, the albumen reappeared, as usual, after each repast.

Charcot's Joint Disease.—At a recent meeting of the Berlin Medical Society a discussion took place upon tabetic arthropathy. Dr. Rotter described the clinical and anatomical features of the disease, with a view of proving its distinct identity and the dependence of the articular changes upon nerve disorder. Professor Virchow followed in a long and careful speech, in which he acknowledged the similarity of the affection to rheumatoid arthritis, and traced the development of the pathological changes in the joints from hyperplasia of the cartilaginous investment, followed by regressive change and atrophy, ossification of the medulla leading to eburnation, hyperplasia, and ossification of synovial fringes, and ultimately of ligamentous tissues. These changes, he declared, were hardly to be regarded as inflammatory; but, although he admitted their dependence upon disordered nerve influence, he maintained that in each case there must be a local determining cause also at work.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, March 12, 1887.

BREHMER'S VIEWS ON THE CAUSATION OF PHTHISIS.

DR. HERMANN BREHMER, of Gürbersdorf, is the widely-known medical director, as he was also the founder, of one of the largest and most successful "institutes" for the treatment of pulmonary consumption ever established. His experience with patients afflicted with phthisis in its various stages is necessarily a very large one. Accurate observation of persons, as well as their diseases, has always characterized the work of Brehmer. For these reasons the conclusions reached by him are of more than ordinary interest to the practitioner. It is, after all, quite as much the individual as the pathological conditions that may be hidden away in his interior, which concerns us as physicians.

Brehmer does not fully accept the far-reaching generalizations of Koch and his followers. In his latest publication, entitled "Die Oetiologie der Chronischen Lungenschwindsucht vom Standpunkt der Klinischen Erfahrung," the author tells us that he has commonly found the lungs of sufferers from phthisis abnormally large, when compared with the size of the abdominal organs and the heart. In this respect he follows the elder Rokitansky, who long ago described a disproportion in the relative size of the organs named. Now, in individuals subject to the peculiarity mentioned pulmonary circulation is always below par. The parenchyma of their lungs is constantly in a condition of malnutrition. Gaseous interchange is less active than normal.

A *locus minoris resistentiæ* is easily established in the lung-tissue. Hence the predisposition to pulmonary mischief.

Flat-breasted persons' lungs are by no means smaller than normal, on the contrary, they are large and unduly elongated. There is more actual, but less potential, parenchyma in such lungs. It will be found that the heart is comparatively small, with a reduced working capacity. A still further cause of diminished blood-supply for the lungs is often present in the shape of pulmonary arteries of lessened calibre. These three factors, then—namely, large lungs, a small breast, and contracted pulmonary arteries—will co-operate in such a way as to make pulmonary malnutrition an inevitable consequence. Without this anatomical predisposition to phthisis the bacillus tuberculosis is almost powerless for evil.

Individuals with large and vigorous heart, with relatively small lungs, and with normally proportioned abdominal viscera do not acquire phthisis. The disease is, therefore, not contagious in the sense usually given to that word when employed to qualify other maladies.

Whatever, then, leads to impaired nutrition may equally predispose to phthisis. Heredity is naturally of considerable moment in this connection. It is frequently observable that unduly prolonged lactation in a mother will imperiously affect the nutrition of subsequently born children. Brehmer gives examples showing clearly that in large families the later-born children are much more liable to consumption than the earlier ones. Faulty nutrition in infancy may lead to actual structural changes of the heart, lungs, and abdominal organs in the direction pointed out above. The author contends that he is thus able to say with great probability which members of a given family are liable or not to phthisis. But perhaps this is only equivalent to saying, though Brehmer does not say it, that persons having the phthisical *habitus* carry with them constantly a soil favorable to the development of accidentally introduced tubercular bacilli. The author certainly does not dwell on this particular point explicitly enough to convince the Kochites of the fallacy of their reasoning.

Nevertheless, it is extremely interesting to follow the author in his account of some five hundred cases of consumption, showing the rather intimate relationship of phthisis to conditions of mental disturbance, epilepsy, deaf-mutism, and the like. The *ultima causa* of these morbid states is claimed to be always an impairment of nutrition. It must be admitted that Brehmer puts his case very forcibly before us. And though his views do not compel acquiescence, they furnish abundant food for reflection, even if they only show that phthisis is a study not yet exhausted, and that the discovery of the bacillus tuberculosis has not made unnecessary continued efforts to obtain still more knowledge regarding so many-sided a subject.

THE DOCTOR'S HORSE.

A CORRESPONDENT asks us to furnish some general advice regarding the purchase of a horse for the country practitioner.

We are much flattered by the request. It is in a measure an admission that THE MEDICAL RECORD can and does discuss all topics of contemporaneous medical interest in a manner which displays certainty of information, soundness of judgment, and brilliancy of literary gifts.

We confess that the doctor's horse is something that seems at first a little outside of the regular lines of scientific inquiry. It will be at once admitted, however, that this noble animal forms a very important item in actual medical practice. It is not only the doctor's means of transportation, but of recreation, conversation, and speculation. Experience shows that next to an interesting case the doctor will talk about his horse with the greatest actual feeling and copiousness. Such a state of things is natural, since next to his professional education the doctor's horse is the most essential thing for his getting along. What avails the transcendent skill of Dr. A while Mrs. B lies in the throes of a crossed presentation ten

miles away, and no horse? At such times the text-books on obstetrics give place beside the Arab steed which each good physician thinks he possesses. And as the mud-splashed gig lightly skims the earth, with the doctor over the seat, and ergot and ether under it, one knows that the doctor's horse is better than a medical course, for it is a medical courser. But the horse in question is not always a pleasure or a help. Balzac once said that, "It was more necessary for the doctor to have a carriage than to cure his patients," a bit of irony in which there is truth enough to cause much pain. The young man who is just beginning to make some progress thinks that he must buy a horse and carriage, to keep up appearances of continued prosperity, and the new establishment keeps him poorer than ever.

We venture the opinion that Balzac's view is not quite true nowadays, and that this setting up an establishment which one can ill afford is both poor policy and poor morals. It is a great many years since Pascal observed that, "If physicians did not have their cassocks and their mules, they would not have duped the world, which cannot resist this show!" Those who succeed in the present day by virtue of their show are deemed quacks, and their success is of a kind that kills self-respect and can have no attraction for honest minds.

Perhaps our correspondent, who seems to be mainly anxious to know how he can get a three hundred dollar horse for fifty dollars, will be disappointed in getting only a homily like the foregoing. We will give him, however, a few practical hints, or, as such things are now in vogue, some "Don'ts" for the Doctor's Horse. Don't, for example, buy a white horse, for that is the color of Death's; and don't buy a black horse, for that is the color of the devil. If you live among the mountains, don't buy a heavy horse; if you live in the city, don't buy too light a horse. If you are a young man, with bills to pay, don't buy any horse at all.

MEDICAL EDUCATION AMONG THE NEGROES.

We have read with interest an account of the recent commencement of the Meharry Medical College, located at Nashville, Tenn. This institution has been in operation about eleven years, and has graduated some sixty men. It now has a Faculty of ten, two laboratories, and a roll of over fifty students, all from the colored population. The people of that section seem to be taking great interest in the cause of the professional, as well as the general, education of the negro, if we can judge from the names of those who honored the commencement exercises with their presence. All of the prominent State and local officials and representative men of the city were on hand. The addresses delivered by the students themselves would have done credit to any of our Northern students. Certainly these young men have opened before them a wide field of usefulness.

Here in the North the problem of how to educate the negroes has never been beset with any practical difficulty. In our large cities separate schools have sometimes been established under the control of local educational boards. No attempt has been made to establish separate technical schools. The colored man has had free access to any of our academical or professional institutions, and has stood, like all others, solely on his own merits.

In the South, however, where the colored population is so great, the question has been a most serious one. Separate technical schools have been established, and most wisely, too. Those acted with the greatest discretion—we think—who established the Meharry Medical College. The negro has had a past with which we are unfamiliar. That this past must contain a wonderful medical history no one can deny. It follows that no class so well as the negroes themselves can unravel this history, after they are properly trained. Back to the "land of Ham" must we go, as the Meharry salutatorian said, "for the first tracing and earliest cultivation of the healing art."

Furthermore, we may express pleasure that in sending forth the graduates of Meharry College to labor in the great field of medicine their instructors have not coddled them, but put them on their mettle. Said one of the speakers to the departing class: "The future depends not upon the color of your skin, but upon the force of your brain, your capacity for toil, and the comprehension you have of your profession." No better advice could have been given.

THE CURE OF COLD ABSCESSES BY IODOFORM INJECTIONS.

The treatment of cold abscesses has long been a subject of dispute among surgeons, some advising immediate evacuation of the pus with scraping of the walls of the cavity, others counselling non-interference. The expectant plan is the one generally followed and often ably advocated by the more conservative surgeons, especially those who have the greatest experience in the treatment of chronic joint disease, but it is not the one favored by the majority of general surgeons. The former contend that those abscesses do little or no harm if left to themselves; either they open spontaneously, usually without causing any pain or exciting any marked febrile disturbance, or the fluid portion of the pus becomes absorbed and the abscess disappears without giving rise to any constitutional disease whatever. The general surgeon, on the other hand, maintains that the presence of pus is always an evil, and that the chance of constitutional infection is an ever-present danger which more than counterbalances the slight inconvenience or risk of an operation.

Within a few years a new method of treatment of cold abscesses has been largely adopted, which is simple, easy of performance, and apparently devoid of risk to the patient. We refer to the use of iodoform injections. Although this plan has been employed for some time on the Continent, it has not as yet been adopted to any great extent by American surgeons, and is, indeed, we believe, not very generally known among us.

It consists simply in the evacuation of the abscess by means of an aspirator, the largest-sized needle being used, and in the subsequent injection of a solution of iodoform in ether. A four or five per cent. solution is the one more commonly used for abscesses of large or moderate size, but occasionally the strength is increased to ten per cent. when the abscess is of very small dimen-

sions. The quantity of solution to be injected varies according to the circumstances of the case, though, in view of the danger of exciting toxic symptoms, it is generally recommended that not more than a drachm of iodoform should be used. The ether holding the iodoform in solution finds its way into every pocket and sinuosity of the abscess cavity, and there deposits a film of iodoform. Some little attention is necessary after the injection has been made, as the ether is rapidly volatilized by the heat of the body, and may cause an unpleasant degree of distention of the abscess cavity. If this occur it may be necessary to introduce the needle of a hypodermatic syringe in order to give exit to the gas. Ordinarily, however, the patients suffer little inconvenience, and are able to go about as usual after the operation.

The experience of those who have employed this mode of treatment has been that one injection is often sufficient to effect a definite cure of the abscess, provided, of course, that it is not directly connected with a centre of disease in a bone or joint which is constantly secreting pus. Sometimes, however, it is necessary to repeat the operation two or more times. The chief inconvenience of this method is the pain which it causes. This is usually pretty severe, and is sometimes so great that the patients prefer to renounce all treatment than to submit to a second trial of the injections. Attempts have been made to find some less irritating substance as a substitute for the ether, but they have not hitherto been very successful.

It is not in the treatment of cold abscesses alone that the iodoform injections have been employed, but they have been used with benefit also in tubercular bone and joint affections. We referred to this method some years ago, when it was first proposed, and we expressed then the hope that experience would demonstrate its utility. And now, if the reports of a number of competent observers in different countries are to be credited, the measure must be accepted as a valuable addition to the therapeutics of tubercular abscesses and joint disease.

POISONING FROM EATING LIVER.

Dr. Carl Lohmeyer, in a learned article in the *Berliner klinischer Wochenschrift* of January 24th, describes the results of eating the apparently healthy liver of a calf. Very few cases of liver-poisoning have ever been reported, and hence this has some special interest. A certain family obtained the liver and other meat from a calf killed the same day. The liver was salted and put in a cool place; next day it was cooked and eaten at a midday meal. The nine persons who partook of it were taken ill very soon afterward. The symptoms were those in the main of cholera nostras. There was also with the profuse diarrhœa a great deal of vertigo, injection of the conjunctiva, and reddening of the face and neck. All the patients recovered in a few days. Investigation showed that the liver was yellower than normal and injected with bile; microscopic examination revealed evidence of an acute hepatitis, just beginning. Tests made by inoculation and feeding failed to give any results upon other animals. There was no evidence of putridity, and other portions of the same animal were eaten with impunity.

The meal which was eaten had been cooked for a long time, and hence any micro-organisms must have been either killed or had their vital energies so reduced as to be innocuous. The result of the study of this case, therefore, led to the conclusion that the symptoms were produced by a septic, chemical virus, which might itself have been the product of micro-organic life.

Cases in which the liver of young animals is diseased in the way discovered by Lohmeyer are very rare, but some instances have been reported.

A NEW THEORY OF MENSTRUATION.

The physiology of menstruation is in a tolerably satisfactory condition, and it seems somewhat a work of supererogation to furnish any new theories about it. The older view of Pflüger, that the mucous membrane of the uterus is thrown off and the surface freshened for the reception of the ovum, has been generally abandoned, and almost all writers are content now with the view that with the approach of the menstrual period a decidua menstrualis is developed for the reception of the ovum, which decidua degenerates and is thrown off if the ovum is not impregnated. Though associated with ovarian activity, this act is, in fact, part of the rhythmical vital processes of the body. As the heart beats, the lungs expand, and all organic muscular fibre moves in a regular cycle, so does the uterus go through its monthly trophic change.

Dr. Arthur Johnstone, of Danville, Ky., has advanced the theory that this monthly process is not so much trophic and vascular as it is secretory and glandular. The endometrium, he claims, is really composed of lymph or adenoid tissue, and menstruation is to it just what the lymph-stream is to the lymph-gland or the blood-current to the spleen.

The explanation for the occurrence of the phenomenon of menstruation in women only, and in some of the higher apes in a partial way, is thus explained: "In two of the ruminants I have shown that nature has supplied this tissue with an abundant lymph-stream, which in the unimpregnated state washes away the ripe material to the general circulation exactly as it does any other lymph corpuscle. But in woman, where, on account of its erect position, the uterus has to depend on the tonicity of its own fibres for the preservation of its shape, no such thing as loose tissue of the lymphatic net-work can be depended on. So to preserve the integrity of the uterine wall, the emulgent stream is poured into the cavity of the body and got rid of by the vagina."

All of which appears to us to be rather vague. Mr. Lawson Tait seems to draw from the views of Dr. Johnstone and of Mr. Bland Sutton evidence favoring the discarded hypothesis of Pflüger, to which we have referred. "We have now," he says, "an explanation of the familiar fact that impregnation and menstruation seem to have a clear relation as to coincidence, the plain fact being that an impregnated ovum adheres only to a surface denuded of epithelium. When desquamative salpingitis has destroyed the tubal epithelium, the ovum may be impregnated in the tube, and may adhere to the exposed surface, and the dreadful issue of tubal pregnancy results."

At least, it is something to learn that tubal pregnancy is caused by desquamative salpingitis. But as for the new theory of menstruation, it can hardly be accepted as yet.

THE TRANSPLANTATION OF A TENDON FROM AN ANIMAL TO MAN.

We have noted in these columns from time to time the attempts, sometimes successful and sometimes not so, made to transplant various tissues, skin, bone, etc., from animals to man to supply corresponding parts lost by disease or removed by the knife of the surgeon. The most striking experiment of this nature is that of supplying a missing eye by one removed from an animal. But possibly the more useful, and certainly the more successful, of these has been the grafting of the less complex tissues, such as bone and skin.

In a recent communication to the Société Médico-pratique, of Paris, Dr. Peyrot relates two instances of the transplantation of tendons. The first case was that of a young man who had received a wound of the middle finger, severing the flexor tendon at the junction of the first and second phalanges. The finger was in a state of forcible extension, and posterior luxation was threatened. This condition had existed for six months, and it was impossible to approximate the ends of the severed tendon by suture. The operator removed from a young dog a piece of one of the flexor tendons of the paw, and, having freshened the ends of the divided tendon in the patient, united them, by three sutures, to each extremity of the transplanted tendon. The wound healed without suppuration, and when the patient left the hospital he was able to execute feeble movements of flexion of all the phalanges of the injured digit.

The second case was that of a young child who had received a similar wound, dividing the flexor tendon of the middle finger at the level of the metacarpo-phalangeal articulation. The ends of the severed tendon were found with difficulty, and were then united to a piece of tendon removed from a dog, as in the first case. The operation was not a success, however, as the foreign tissue sloughed away.

The insertion of a tendon would clearly be required only when there has been an actual loss of tissue, or when the separation has existed for so long a time that reunion by direct suture is impossible. But when such a condition exists, the success obtained by M. Peyrot in his first case would seem to warrant the attempt to supply the defect by the insertion of a tendinous graft from one of the lower animals.

THE SURGICAL TREATMENT OF CERTAIN LIVER DISEASES.

Dr. George Harley has recently published in one of the London journals some observations on hepatic phlebotomy, together with the puncture of the capsule of the liver in certain affections of that organ. He admits that it is no new procedure. It was done in India nearly forty years ago, and has been practised in London for the last two decades. At first a large tube, the size of a No. 12 male catheter, was used. On account of the resulting hemorrhage the size of the tube was gradually reduced, until now an ordinary aspirating-needle is used.

Naturally, many different physicians have tried this procedure, and many of them have recorded their disappointment at their results. Dr. Harley calls attention to the fact that this operation, like all others, has its limitations and essential conditions of success. Disappointment has resulted from a lack of regard concerning the vascular distribution in the liver and the relations of the site of puncture to the interior of the anterior abdominal wall. In Dr. Harley's hands no failure has resulted from an experience of twenty years. He uses an exploring-trocar about seven inches long. This is attached to an ordinary syringe of a drachm capacity, which exerts an aspirating force.

If this exploratory puncture reveals the presence of pus, and it flows with difficulty, the above instrument is replaced by a larger one, which is connected with a rubber ball and siphon arrangement. By this means the drainage of the pus is facilitated, and an excess of aspiration prevented. If the liver-tissue happens to be softened, as the result of pathological change, there is danger of withdrawing through the needle softened liver-tissue, unless great care be taken not to make the suction-force too great. The large vessels should be avoided. The site of puncture should be such that after the withdrawal of the needle the wound in the liver can, by means of firm pressure with an abdominal pad, be brought into close apposition with the anterior abdominal wall. The wound in the skin is simply covered with a small piece of sticking-plaster.

The operation is contra-indicated whenever the liver is affected by cancerous, fatty, or waxy changes. In congestive hepatic hypertrophy the puncture of the capsule of Glisson seems to give some relief.

THE SEPARATION OF THE LICENSING FROM THE EDUCATIONAL FUNCTION, IN MINNESOTA.

Minnesota has for four years had a law regulating medical practice, which law has accomplished a great deal in elevating the status of the physicians of that State and in protecting the public from charlatanry. The law was defective in some points, however, and has now been superseded by another, which seems to contain almost all the desirable features of good medical legislation.

Dr. Perry H. Millard writes us that the main features of this law are: 1. The appointment of a Board of Examiners by the Governor. 2. No member can serve to exceed two terms in succession. 3. Two members are to be homœopaths. 4. All persons hereafter commencing the practice of medicine in the State must pass an examination upon the different branches. 5. Before entering upon said examination they must produce evidence of having attended three courses of lectures, if date of diploma is later than 1887. 6. Power is given the Board to refuse or revoke license for unprofessional, dishonorable, or immoral conduct. 7. No member of any existing medical faculty eligible to appointment upon new Board.

The last section is an especially satisfactory one, since it divorces entirely the licensing from the teaching power.

This is what we are needing in New York State, and the lukewarm support which the present bill at Albany receives is due to the fact that it is felt, after all, to be a medical-college affair.

A NEW BUILDING FOR THE WOMAN'S MEDICAL COLLEGE OF THE NEW YORK INFIRMARY.

A CALL has been issued for a public meeting, to be held at Chickering Hall, Monday, March 14th, in the interests of a new building for the Woman's Medical College of this city. Mr. D. Willis James will preside, and speeches are to be made by Drs. William H. Draper, Emily Blackwell, J. West Roosevelt, Mary Putnam-Jacobi, and Mr. Joseph H. Choate. The call for the meeting has been signed by a large number of well-known public citizens.

Already a considerable sum of money has been subscribed, and it is hoped that a fund of $100,000 will be obtained. The Woman's Medical College of this city has won a deserved reputation for being conscientious and thorough in the education of its students. Its work has been handicapped by the lack of funds and of a suitable building; so that although New York, by virtue of its vast clinical opportunities, should be the centre for the medical education of women, it, in fact, barely holds its own with smaller cities.

FAITH-CURES AGAIN.

REV. DR. J. H. BUCKLEY returns to his attack upon the faith-curers in the March *Century*. He brings further evidence to show that there is nothing supernatural in their work, but that it is entirely similar to the cures made by spiritualists, voudoos, and magnetic healers.

On one point alone we think that Dr. Buckley has failed to lay sufficient evidence, and that is the evil which this sort of thing eventually works. The physician, over and over again, comes across illustrations of failures of the faith-curer, and he observes that the effect upon the patient's mind is bad. The will-power of one who has once been hypnotized is enfeebled, often permanently; and the process of faith-cure is a form of mesmerism. Persons benefited for a brief time through the stimulus of emotional excitement relapse into a worse state than before. It is a kind of emotional intoxication, and the mind suffers from it as from all morbid stimulants. So far from faith-curing and magnetic healing taking away the work of the physician, it actually adds to it; and nothing probably would give a larger field for the work of the neurologist and alienist than a wide-spread indulgence in faith-curing.

THE EMBALMING OF BODIES AND PRESERVATION OF SUBJECTS FOR DISSECTION.

IF we cannot save our patients, we can at least preserve our subjects. This is the text upon which Professor S. Laskowski, of Geneva, writes, in a memoir crowned by the Academy of Sciences of Geneva.[1] His work is an interesting one; and as the main facts contained in it can be easily condensed, we venture to present them to our readers.

Professor Laskowski reviews first the history of embalming. Of ancient nations the Egyptians, as is well known, reached the greatest perfection in its practice. But, after all, their methods were crude and empirical, and their success depended chiefly upon the remarkable dryness of the climate.

The Egyptians simply eviscerated the body, stuffed it with aromatics, and bandaged the body with cloths saturated with gums and aromatic substances. The body was thus preserved long enough for dissection to take place, when putrefaction became impossible.

Embalming was resorted to again in the middle ages, when bodies were again eviscerated, and the limbs and trunk cut into. Balsamic substances were then inserted and the wounds sewed up.

It was not until the present century that embalming and the preservation of subjects was undertaken by means of injections into the vessels. Dr. Franchina, of Naples, and, at almost the same time (about 1835), Lauth, of Strasbourg, conceived the idea of forcing preservative fluids into the blood-vessels. This plan has been followed with various modifications ever since. Franchina first used a five-per-cent. solution of arsenious acid. This preserved the subject, but made it very poisonous, and rendered dissection not free from danger.

Gaunal, of Paris, devised a method which was successfully followed for some time. It consisted in placing the subjects for two months in a solution composed of nitrate of potassium, 1 part; chloride of sodium, 2 parts; alum, 1 part. Later he substituted arterial injections of a saturated solution of neutral sulphate of alum. Subsequently, various solutions containing zinc, sulphite of soda, corrosive sublimate, etc.

None of these, according to Laskowski, were free from objections, and he announces as the ideal injecting-fluid a solution first devised by himself in 1864. This solution consists simply of glycerine of second grade in quality, 100 parts; carbolic acid, 5 parts. Of this from four to six litres are used at a cost of about eight francs. A somewhat cheaper fluid which answers very well is glycerine ambrée, 100 parts; alcohol (or water), 20 parts; carbolic acid, 5 parts; crystallized boric acid, 5 parts. Cadavers injected in this way remain free from decomposition for several months. Even if decomposition has already begun, the injection will stop it, and preserve the body.

Professor Laskowski claims that by modern methods the embalming of the body can be done much more perfectly than was the case in ancient times. Embalming, however, is now, as in ancient times, a luxury which few can afford, and its success calls for a great deal of technical skill. The fluid used consists of 7 litres of pure glycerine, 250 grammes of carbolic acid, 500 grammes of chloride of zinc, 1 kilogramme of absolute alcohol, and 250 grammes of corrosive sublimate. Some special manipulations are required in order to mix these ingredients properly. After it is made, such essences and tinctures are added as may be desired to produce agreeable odor and color.

The vessels are injected with this fluid, the greatest possible care being taken not to rupture any vessels. Flannel bandages saturated in the solution are also bound about the limbs and trunk. Bodies so prepared and exposed to the air in vaults have been preserved for twenty years. In one case a body so embalmed and buried was examined eighteen months later, and very little change was found.

[1] L'Embaumement la Conservation des Sujets et les Preparations Anatomique, par Le Docteur S. Laskowski. Genève—Bale—Lyon: H. Georg, 1886.]

News of the Week.

The Medical Department of the University of New York held its Annual Commencement on March 8th, and graduated a class of 151. The address to the graduates was delivered by Rev. Dr. John R. Paxton.

Cholectomy.—Professor Langenbach has recently reported a successful removal of the gall-bladder, which was diseased and full of gall-stones.

Thoracic Lung Hernia.—A strongly built child, eight months old, suffered from whooping-cough, and after one of the paroxysms developed a protrusion in the mammary line between the sixth and seventh ribs. This was found to be an actual hernia of the lung. The case was reported by Dr. Adler to the Berlin Medical Society.

An Increase of Local Temperature over the Spleen has been found by Dr. Montefusco, of Naples, in variola. This local increase is about 1° C. higher than the cutaneous temperature elsewhere, and varies with the course of the fever.

The Long Island College Hospital held its Twenty-eighth Annual Commencement on March 2d, and graduated a class of thirty. This excellent institution continues to prosper, despite of the nosological inversion under which it suffers. It is a college—not a hospital—which holds the commencements. Some day we trust the topsy-turviness will be corrected.

Twenty Years in Prison for Blowing up a Physician.—The Maine method of dealing with doctors who are out when a patient calls is described by the *Lewiston Journal* as follows: "A physician in Monson went out of town when a certain person's child was sick. The child died; the father thereupon blew up the doctor's office with dynamite, saying that he did it for revenge—claiming that if the doctor 'had staid at home and attended to his business' his child would have lived. The doctor is sufficiently 'blown up' for his sins, but to have his office blown up is carrying things beyond physiological limits. The Maine dynamiter was sent to prison for twenty years."

A Pathognomonic Symptom of Tubercular Meningitis.—Dr. J. D. Skeer, of Chicago, writes us on the above subject, regarding which an editorial appeared in The Record of some weeks ago. At that time we made the suggestion that syphilis, as well as tuberculosis, might possibly produce some such appearance of the pupil as Dr. Skeer describes. The point at least was worth consideration. We regret that Dr. Skeer misconceived our meaning, and has chosen to think that it implied anything regarding his own family.

Dr. W. S. Searle, the attending physician of the late Henry Ward Beecher, is a native of New Hartford, Oneida County, N. Y. He graduated in the arts at Hamilton College with high honor in 1855, and in medicine at the University of Pennsylvania in 1859. He is a member of no school especially, but although ranking among the homœopathists does not belong to any of their societies. He is a regular, but liberal in every particular. He is the author of one or two monographs of value.

It is a Consumptive Locality.—It is hard to please everybody. We ventured to state, a few weeks ago, on the authority of a correspondent from that place, that Tarborough, N. C., was quite free from consumption, and getting to be quite a health-resort. A physician from that town writes that our note "does the physicians of the place great injustice." Tarborough, he says, does have phthisis, and has its share. In reference to this statement, we beg to remove Tarborough from the heights of salutary greatness upon which we placed it, and we withdraw the unjust remark of calling the town healthy. We shall be willing, if this is not sufficient, to concede that Tarborough is rank with miasmatic disorder and that its streets re-echo to the hollow coughs of innumerable home-bred consumptives. We express remorse at having suggested that Tarborough was a place worth living in, and hope that we have now done full justice to it and its able faculty.

Temperance and Drug-stores in Kansas.—Dr. J. M. Evans, of Chillicothe, O., writes: "It is doubtless true that some unscrupulous druggists in Kansas have violated the spirit of their prohibitory laws in the sale of liquors; but every intelligent reader of your excellent journal knows that your quotations from the Oswego City *Free Press* are overdrawn, and that the representation that the drug-stores throughout the State of Kansas are taking the place of the open saloon is not true." Our correspondent concludes with some animadversions upon The Medical Record, which, as they do not bear on the argument, we venture to omit.

Dr. John G. Westmoreland, of Atlanta, Ga., died on March 3d, in the seventy-second year of his age. Dr. Westmoreland graduated in medicine at Augusta, in 1841. In 1855 he founded the Atlanta Medical College, and continued to hold a prominent place in medical circles of that city until his death.

The Overcrowding of the Profession in the Australasian Colonies.—The *Australasian Medical Gazette* says that the number of medical practitioners arriving in the colonies each year is very much in excess of the proportion it should bear to the increase in the population, when a due prospect of success is considered. It says that local schools are turning out an excess of young medical men. Medical overcrowding is evidently an affection characteristic of growing countries.

Hebrew Physicians in New York.—A writer in the *Mail and Express* states that there are nine hundred Hebrew physicians in New York. This would make about one-third of the total number.

Successful Tracheotomies.—Diphtheria is epidemic in Hamburg, and in the past year tracheotomy was performed 157 times at the General Hospital, with 69 recoveries. This goes ahead of intubation.

A Heart-tonic in Adynamic Fevers.—Cocaine is recommended as a heart-tonic and stimulant in low adynamic fevers. The dose is gr. ¼.

Phthisis and Race.—Dr. William Pepper's study of phthisis in Pennsylvania shows that this disease prevails (in Philadelphia) more among the foreign-born and negroes than among the native whites; but less among the Jews than among the general population.

A Controversy in the Surgeon-General's Office at Washington.—The daily papers state that Surgeon-General Moore and the Secretary of War are at odds over the question of who controls the office. It is said that the Secretary, without consultation with the Surgeon-General, sent Dr. Huntington to San Diego, Cal., and placed in his stead at the Surgeon-General's office, Dr. Greenleaf, of Chicago, a gentleman personally distasteful to Dr. Moore. The Surgeon-General remonstrated, and has now appealed to the President.

Celebrity No. CCCCXCII.—Under the title of "Celebrities at Home, No. CCCCXCII.," the London *World* gives an interesting sketch of Mr. Ernest Hart in one of its recent issues. Mr. Hart was at one time an ophthalmic surgeon, but gave up practice to assume the editorship of the *British Medical Journal*. He is a devotee of Japanese art, and has a large collection of Japanese bric-à-brac. "The secret of his vast capacity for work," we are told, consists "in love of order, his power of organization and his extensive utilization of short-hand." Mr. Hart well deserves the distinction to which he has attained.

Lady Dentists.—The committee of the National Dental Hospital of London have resolved to admit registered lady medical students to the practice of the hospital.

A National Association of Genito-urinary Specialists has been organized.

The Ten Most Useful Books.—*Technics* asks its readers what are the ten most useful books, and the ten most useful remedies for the general practitioner. For the former list there may be suggested, the Bible, Shakespeare, Hippocrates, Pickwick Papers, Schopenhauer, the U. S. Dispensatory, standard works on General Medicine, Surgery, Obstetrics, and, finally, a bound series of The Medical Record!

The International Medical Congress.—The item appropriating $50,000 for the Congress was placed in the Sundry Civil Appropriation Bill, and was therefore, we presume, passed. If so, this sum will be a great help in promoting the success of the Congress. Several steamship lines have reduced rates to $80, $90, and $100 for the round trip across the Atlantic.

After-treatment in Iridectomy and Cataract Operations.—Dr. J. J. Chisolm, of Baltimore, now simply secures the lid of the eye operated upon with isinglass plaster, the other eye being left untouched. The patient is treated simply as if he had a cornea-wound.

"The New Quinine."—The much advertised nostrum "Kaskine" has been analyzed by Dr. F. B. Power and Dr. Bennett F. Davenport, at the request of Dr. Fr. Hoffmann (*Pharmaceutische Rundschau*). It was shown a year ago to be nothing but granular sugar. Now it is found to contain a minute trace of quinine. Each pellet contains about $\frac{1}{1000}$ of a grain.

The Title of "N.C.S.D."—A man recently appeared before the Rhode Island Legislative Committee to testify as to the benefits of quackery and the need of giving everyone a chance to practise medicine. His name was "Baxter, N.C.S.D.," which letters were found to stand for "Natural Common Sense Doctor." In his opinion diplomas did not amount to a row of pins, as they could be purchased in Philadelphia not long ago for $5 a bushel. He believed the law should provide that everybody who practised medicine should be placed under bonds to do as he agreed, and if a failure to do so occurred, the money should be refunded. If the doctor agrees, or assumes, to effect a cure, and the patient dies, the doctor should pay back all the money he has received, and pay funeral expenses. All of which seems to show that Mr. Baxter was modest in calling his common-sense natural—it is nearer supernatural. But he was not far out of the way in his estimate of the diplomas at present obtainable.

Death in the Bridges.—In 1857 sixty persons were killed on the Great Western Railway, at the Des Jardines canal bridge. In 1867 forty-eight persons were killed by an accident on a bridge on the Lake Shore road. In 1876 seventy-five persons more were killed on the same road, at Ashtabula. In 1878 the Tay bridge accident cost the lives of ninety persons, and recently, at the White River bridge, over sixty (?) persons were killed.

The American Veterinary College held its Twelfth Annual Commencement on the evening of March 4th, when a class of forty-four was graduated.

Meat and Tuberculosis.—The New York Academy of Veterinary Science and Comparative Pathology, a society with a rather heavy name for its light membership, held a meeting in this city last week. Some resolutions were presented which are in the line of present work of preventive medicine. They stated that during the past year 37,330 deaths had occurred in New York City, and of this number 16,000 were those of children under five years of age. The Academy believe that many of the deaths were caused by diseased meat and adulterated milk. There were only four milk inspectors and one meat inspector, and the Academy urged the establishment of public abattoirs where cattle could be examined before and after being slaughtered, and also for the establishment of milk depôts for the examination of milk. The number of inspectors should be increased, and every candidate should first be examined by a commission, to consist of one member from the Board of Health, one from the Microscopic Society, and one from this Academy. An amendment was added to compel every veterinary surgeon to report to the Board of Health all contagious diseases of animals that might come under his notice.

We Learn that Dr. D. B. Simmons, who recently visited this country, received a genuine ovation upon his return to Yokohama. Dr. Simmons has practised medicine in Japan for over twenty years and has been connected with the organization and development of the important governmental sanitary work in Japan, besides conducting a large hospital, teaching, writing, and practising.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN PRACTICE.

Stated Meeting, February 15, 1887.

WESLEY M. CARPENTER, M.D., CHAIRMAN, *pro tem.*

SYPHILIS IN RELATION TO VISCERAL LESIONS AS A CAUSATIVE AGENT, ESPECIALLY IN PHTHISIS.

DR. WM. H. PORTER read a paper on the above subject (see p. 285).

DR. FRANCIS DELAFIELD was invited to open the discussion, and said that he had listened with interest to the paper, but found some difficulty in discussing it because of the few points on which he should be disposed to agree with its author. The poison of syphilis certainly sets up inflammation in many different parts of the body, and, roughly speaking, the effects could be classed as acute, subacute, and chronic. There was nothing special concerning the acute process to distinguish it from acute inflammation due to other causes. The subacute inflammation was characterized by the production of granulation-tissue, practically, which was short-lived and had a disposition to necrosis and cheesy degeneration, and might arrange itself into gummy tumors. With this production of granulation-tissue there were, regularly joined, changes in the walls of the arteries, and also acute endarteritis with a tendency to obliteration of the vessels. Besides, there was chronic inflammation, the result of syphilis, and the prominent feature of this was the formation of new connective tissue, with the same changes in the blood-vessels.

When it came to the lungs it seemed to him that these conditions could be found there. There might be acute lobar or broncho-pneumonia which, anatomically, did not differ from the pneumonias due to ordinary causes. There was a chronic form of inflammation of the lung in which the chief change consisted in the production of new connective tissue, and it followed either the type of broncho-pneumonia or interstitial pneumonia, involving principally the root of the lung. With either of these, gummy tumors might be present or absent. That was all that he knew about syphilitic lesions of the lungs; and if the illustration presented represented the typical form of pulmonary syphilis which the author of the paper wished to describe, he should suppose it was an exceedingly good one of chronic miliary tuberculosis. While it was seemingly ungrateful and apparently discourteous to discuss in this manner the conclusions which had been formed as the result of long observation and careful study, yet these conclusions were so entirely erroneous, and so likely to do harm instead of good, that at the risk of the apparent discourtesy he must express his own opinion without reserve.

DR. W. H. DRAPER said that he found himself substantially in the position described by Dr. Delafield. He was not at all convinced, from an anatomical stand-point, that many of the cases described by Dr. Porter were not cases of tubercular phthisis. But it was from a clinical stand-point, especially, that he would be inclined to differ with the author of the paper. He thought it was impossible to make any such differentiation, clinically, as had been made between syphilitic and tubercular phthisis; for the reason that the clinical history of tubercular phthisis varies so much, and he was sure that the experience of anyone who had seen much of tubercular phthisis would readily recall cases in which the clinical picture given of syphilitic phthisis could be reproduced.

In other words, the febrile history of tubercular phthisis differs very markedly in different cases. So also does the amount of dyspnœa and all the physical signs of tubercular phthisis.

His own clinical experience in phthisis with relation to syphilis was very limited. About ten years ago he was called to see a woman who had contracted a chancre of the lip from her husband. She had marked syphilitic fever and the typical evolution of the syphilitic disease. Within two months from the time of the development of the chancre he discovered signs of pulmonary disease in the right lung, which progressed rapidly and presented the prominent symptoms of tubercular phthisis, of which she died at the end of eighteen months. He believed it to be a case of tubercular phthisis, and was of the opinion that all syphilographers agreed that the phthisis which follows syphilis is tubercular in character. Most syphilographers also mention the fact that syphilis is a determining cause of tubercular phthisis. He had not seen any other case in which the relation was so marked as in that just related.

DR. F. N. OTIS had been much interested in Dr. Porter's elaborate paper, but he was surprised at the outset to learn that Lustgarten's claim in regard to the discovery of the bacillus of syphilis was supported by Dr. Porter's investigations. The observations of MM. Alvarez and Tafel (undertaken at the suggestion of Professor Cornil, of Paris, for the purpose of testing the validity of this alleged discovery) were published in the "Bulletin of the Academy of Medicine of Paris," for August 4, 1885, and were there claimed by Professor Cornil to have proved that the bacilius in question was not peculiar to syphilis. That while it was often found in the secretions of syphilitic lesions, it was also found in the normal smegma and in other secretions of the genital organs of both sexes—not syphilitic, and more recent observations by other investigators have further disproved Lustgarten's claims.

Lostofer and Klebs, who preceded Lustgarten in the alleged discovery of the true pathological principle of syphilis, each claimed to have discovered the peculiar micro-organism in the tertiary lesions of syphilis, which through numerous experiments by inoculation had been previously shown to be free from a contagious element. The rediscovery of this element in Lustgarten's bacillus again raised the question, and the subsequent elimination of this bacillus of Lustgarten left the question resting on the negative results of inoculation previously alluded to. It seemed to Dr. Otis, however, that the statistics of M. Alfred Fournier, in his work on "Syphilis and Marriage" (Paris, 1880), at last had settled this important matter beyond a question, and made it necessary for future discoverers of the specific bacillus of syphilis to confine this micro-organism to the lesions and secretions of the active period of syphilis. Fournier cites 87 consecutive cases, occurring under his own observation, where men who had had syphilis married within an average of five years from the date of the acquirement of the disease, and who never communicated to their wives the least suspicious phenomenon; and, moreover, these 87 produced among them 156 absolutely healthy children. Thirty-six out of this number of men who had been thus proved to be free from any power to transmit syphilis, either by direct contact or by heredity, were subjects of late or tertiary lesions after marriage, some before and some after the birth of children. These lesions comprised almost all the varieties of the sequelæ of syphilis. This enormous mass of evidence, consisting of 87 authentic consecutive examples, involving prolonged observation of 330 individuals by a competent observer like M. Fournier, may, Dr. Otis claimed, be accepted as settling in the negative the question as to whether or not there is a contagium in the tertiary lesions of syphilis.

Another important question was raised by Dr. Porter, one which had long been a subject of controversy in the medical profession, and that is in regard to the manner in which syphilis is transmitted by heredity. Dr. Porter claimed that the product of conception might be infected by the father alone, the mother escaping entirely. This view, Dr. Otis was aware, is upheld by various authorities,

and apparently trustworthy clinical observations have been adduced which would seem to support it; but he believed it to be a fact that could be generally accepted, that as many cases of syphilis could be brought forward in which the disease had run its course through the active stage without being discovered as there were in which the child had been apparently infected by the father, the mother having escaped. He believed it would be found that in all these cases the mother has had syphilis, but in a form so light as to have escaped observation.

In all the recent leading works on syphilis it is distinctly stated that the natural secretions do not contain the contagium of syphilis, and among these natural secretions the *semen* is especially mentioned. If this be the fact, it would be interesting to know how the male has access to either the ovum or the placenta.

He would claim, then, that under all circumstances syphilis must be first communicated to the mother before the child can have the disease.

With regard to the cases which constituted the subject of the paper, Dr. Otis would designate it as syphilis of the lung rather than syphilitic phthisis. The conditions in syphilis of the lung do not differ in many instances from the results of ordinary pulmonary phthisis, because there is not necessarily anything characteristic in the pathological conditions, as there is nothing specific in the macroscopic appearances in either. Virchow has stated that even in a case where syphilitic gumma were present in the other organs, and he considered the lesion in the lungs syphilitic, the pathological appearances were doubtful. The term phthisis usually implies a tuberculous affection, and suggests a treatment quite opposite to that which we should employ in a case of syphilitic disease of the lung in the tertiary stage. The occurrence of any disease of the lung, as well as of any other organ, resisting ordinary measures in a person once the subject of syphilis, should suggest syphilis as a possible cause of the trouble, and the test of treatment, especially if emaciation is not present, should be applied. The concurrence of late syphilitic lesions at other points constitutes one of the most important aids to a correct diagnosis, and warrants the administration of anti-syphilitic measures to the same extent as if no pulmonary disease were present, it occasionally happening that on the bare suspicion of phthisis mercury and the iodides are either withheld or greatly modified.

Dr. R. W. Taylor spoke from a clinical rather than a pathological stand-point. He thought that it was peculiar to all pathologists and anatomists whose arenas were the microscope and the dead-house to paint terrible pictures of the malignancy of syphilis. He was not one of those who depreciated the malignancy of the disease, but at the same time it was undeniable that very many cases ran a benign course under proper treatment, and the converse was true that the disease would run a severe course if no remedies were taken. There were three essentials to a benign course or a cure of syphilis: 1, A good constitution; 2, a docile patient; and 3, a good doctor.

There were, however, some cases similar to that related by Dr. Draper. In 1872 he saw one in which the patient had been committed as one having small-pox. The disease pursued its course uninfluenced by treatment. After the patient had been out about two weeks he had an attack of what seemed to be broncho-pneumonia, and died in the sixth week of his illness.

Other and similar cases, where the patients have undergone treatment, have been observed. But that the disease did occur, scattered throughout the lungs, and had been cured, he thought the following case would prove. In the spring of 1876 he saw a young Hebrew who was laid up with rheumatic pains and roseola. He had had a urethral chancre. He went through the stages of syphilis during the summer, and early in the next winter he caught cold, as he thought. His breath was short, emaciation followed, his appetite waned, and he sought the advice of a physician. There was slight dulness at the right apex, with rough respiration, and a similar condition at the apex of the left lung, though not so marked. Dr. Taylor regarded the lung trouble as one due, in a measure at least, to syphilis. Dr. W. H. Thomson saw the patient and gave the opinion that it might be due to more than one condition; possibly pulmonary, and possibly produced by the former disease. He diagnosticated localized pleurisy, with peri-bronchitis at the apex on the right side, and a less degree of the same conditions at the left apex. The mixed treatment was continued, and in February, one month after the consultation with Dr. Thomson, there was a marked improvement. During the next summer his health was good, and Dr. Thomson again examined the patient and reported that he found no evidence of the morbid process; and six months afterward Dr. Loomis said that he was unable to detect any pulmonary disease.

According to his experience, then, there were two classes of cases: 1, That of which the first case mentioned was an illustration, acute in character; and 2, that where localized deposits exist in the lungs, pursue a chronic course, and under treatment improve or are cured.

With regard to one point he was totally in discord with Dr. Otis, and that was as to the statement that a mother in order to have a syphilitic child must necessarily be syphilitic.

Dr. F. R. Sturgis regarded the term "syphilitic phthisis," as a very unfortunate one, as there was nothing clinically to distinguish it from ordinary tubercular phthisis. He thought that it would have been better to have recognized this fact, to have recognized that there may be gummatous infiltration of the lungs, and to have dropped the terms pneumonia and phthisis entirely. Then we could speak of a diffuse and a circumscribed gummatous infiltration.

There was one point at which he thought that Dr. Porter was defective in his reasoning. Undoubtedly the hyaline changes mentioned were found in these syphilitic lungs, but would Dr. Porter be prepared to say that in every case in which it was found it was due to syphilis? Probably he would not be willing to take that position. Without question there were hyaline changes, apart from syphilis, and attended by breaking down of tissue. If so, the whole fabric upon which the paper had been built fell to the ground. A syphilitic subject may have broncho-pneumonia, or phthisis, etc., the same as other persons, and when this complication does exist it is extremely unfavorable for the patient.

With regard to the question of a bacillus. If all were in accord with Lustgarten, Dr. Porter's case would be a very strong one. But is there a bacillus that produces syphilis? Lustgarten's is questioned. All know how Lostofer's corpuscle came to naught, and how others have been disproved. Lustgarten's remains as the only one entitled to consideration, and by many syphilographers this is not accepted. Because bacilli are present it does not necessarily follow that they are due to syphilis, or that they cause it.

Again, with reference to treatment, this by no means proves that a given lesion is syphilitic or non-syphilitic.

Concerning the syphilitic child without the syphilitic mother, he thought that the great preponderance of evidence was in favor of the view that infection of the child without infection of the mother does not occur. Indeed, the only case that really supported the view that the child can be infected by the father alone was that reported by Dr. Taylor, and even that had some points at which doubt might arise.

Dr. E. B. Bronson directed attention to one symptom on which the reader of the paper had laid special stress; namely, tenderness, pain, and œdema over the sternum and tibia, a symptom to which Dr. Bronson believed an undue amount of importance had been attached. He had yet to see a case in the late stage of syphilis in which it was present.

Dr. H. Biggs said that altogether too much importance had been attached to the presence of Lustgarten's bacillus, as the evidence that it had any bearing on the existence of syphilis was very slight. It had been found in the vesicles of herpes by several observers, was present in the tissues in only very small numbers indeed, and it seemed to be accidental rather than otherwise, and the bacillus was absent in syphilitic pharyngeal and laryngeal affections.

With regard to the absence of tubercle bacilli, he could not help believing that Dr. Porter's observations had been erroneous. It was very rare that tubercle bacilli were absent in cases of tubercular phthisis, and he would not attach very much importance to the microscopical observations, because the staining reaction of the bacillus of Lustgarten and that of the tubercle bacillus were very similar; so much so, that he thought Dr. Porter had mistaken the one for the other.

As to the clinical history, he had had quite a large number of cases under observation at the workhouse on "the Island," which were undoubtedly in syphilitic subjects, and no better results had been obtained by specific treatment than by the treatment commonly adopted in pulmonary tuberculosis.

Dr. Porter, in closing the discussion, said he was well aware that many of the microscopic appearances, which he had described as being rather characteristic of the syphilitic lesion, were similar to those described in connection with the tubercular process. In the tubercular cases, however, he had been unable to find the peculiar hyaline degeneration which he had seen in the syphilitic cases, and had, therefore, come to regard it as rather characteristic of the latter affection, and, finally, that it was absolutely diagnostic of the syphilitic taint.

With reference to the bacillus of Lustgarten, he had not been a very positive believer in its value, but to eliminate any doubt he had had the specimens examined by those who were familiar with the bacillus, and they had reported that those present were not the bacilli of tuberculosis. If tubercular, of course they would exclude syphilis; or they might not necessarily exclude that disease. For a bacillus, stained according to Lustgarten's method, was always found in the centre of the masses called gummatous tumors, and it was this fact that seemed to go toward establishing the belief that, in many cases, the child could become syphilitic through the father without infection of the mother. Again, very many of the cases responded to anti-syphilitic treatment, not having improved under the forms usually employed in the treatment of pulmonary tuberculosis.

The Section then adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, January 26, 1887.

T. Mitchell Prudden, M.D., President, in the Chair.

The President announced, as

THE COMMITTEE ON MICROSCOPY

for the ensuing year, Drs. G. C. Freeborn, W. H. Porter, and J. S. Thatcher.

Dr. W. H. Porter presented

A HEART WITH A DOUBLE MITRAL ORIFICE,

probably congenital, but he had been unable to find mention of this peculiar malformation.

There were two other interesting features in the case. The man was admitted into the Chambers Street Hospital, where the diagnosis of uræmia was made, and he was transferred to Bellevue Hospital, where it was recorded that he had considerable serous and blood-stained discharge from both ears, and the diagnosis of

FRACTURE AT THE BASE OF THE SKULL

was made, although there was no paralysis. Death occurred a few hours afterward. The autopsy did not reveal any fracture whatever of the skull.

The other interesting fact was that the man had

A DEEP URETHRAL STRICTURE,

which illustrated one reason for not treating these strictures by internal urethrotomy; that is, the stricture was upon the *floor* of the urethra; the roof of the urethra was normal.

Dr. Porter also presented a microscopic section, made from the cortex of the brain, that showed

A SINGLE MILIARY ANEURISM

very distinctly; the globular swelling involved the whole diameter of the little vessel.

CHRONIC PACHYMENINGITIS—ACUTE LEPTOMENINGITIS.

Dr. L. Emmett Holt presented specimens taken from a female child, twenty months old, with the following history:

The patient was one of a pair of twins, the mother and the other twin having died of tuberculosis. She had always been delicate, and in August, 1886, had a febrile attack, lasting nearly two weeks, with a temperature ranging from 102° to 105° F., for which no explanation could be found. There was a moderate amount of albumen in the urine, but no casts. The fever gradually subsided, not being influenced in its course especially by any of the agents employed. There were no marked cerebral symptoms. Ever since that time the child had remained in a rather dull, listless condition, but not particularly drowsy, and gave no signs of pains in the head or elsewhere. She did not thrive, her weight remained stationary, and her tissues were soft and flabby. She was frequently examined with the idea of the possible development of tuberculosis, but no signs could be found in the lungs to indicate disease of any character. Only two prominent symptoms were present—an irregular febrile movement and an enlarged spleen. The evening temperature generally touched only 100° or 101° F., but every week or two a sudden elevation to 104° F. would occur without assignable cause. This was true of the three months preceding her death. The spleen could easily be felt below the ribs.

Quinine was tried in full doses without benefit; then mercurials, by inunction, and later by the stomach, with the idea of a possible syphilitic element in the case. Improvement seemed to follow this plan for a time, and the enlargement of the spleen sensibly diminished, but these changes for the better were but temporary.

Four days before death very marked cerebral symptoms developed. The temperature rose steadily from 101° to 104°, then to 105½°, and finally, on the day before death, to 108° F.

The respirations became irregular, shallow, and finally typically Cheyne-Stokes; pupils equally contracted; slight rigidity of the muscles of the upper and lower extremities, but no paralysis; abdomen tympanitic; stupor increasing to coma, and then death without convulsions, either local or general, and with no focal symptoms at any time during life.

Autopsy, forty-eight hours after death.—Body small, poorly nourished; fontanelle open, ¾ × 1 inch in size. Head: Pretty strong adhesions between dura and pia over frontal lobes, especially of right side. Inner surface of dura over about one-half its extent, and most abundant near the median line at convexity, covered with jelly-like lymph of a yellowish-green color, fully one-fourth inch thick. Beneath this recent deposit a pretty tough false membrane was present, which again was separated from the dura by a thin clot partially organized, but not completely discolored, and covering an area

about half the size of one's hand. The false membrane could be demonstrated as far as midway between the sagittal suture to the base of the skull. Over the left side of the convexity a very thin false membrane existed, not nearly so extensive, but no clot or recent lymph was present. The superior longitudinal sinus contained a firmly organized thrombus, which was not adherent. The pia over the whole convexity, and over the base to a less degree, was covered with recent lymph and pus, very abundant everywhere, giving the brain a greenish appearance. The brain-substance to the naked eye showed no changes; the ventricles were empty, and no tubercles were seen anywhere. Chest: Lungs and heart normal. Spleen: Weight one and one-eighth ounce; firmer than usual; size about normal. Liver normal. Kidneys showed marked cloudy swelling both to naked eye and to the microscope, but no further changes; weight three ounces. Intestines showed old thickening of the mucous membrane, but no evidence of recent inflammation. No tubercles in any viscus.

The case was of interest chiefly from the clinical history and the indefiniteness of the symptoms until a few days before death.

No symptoms were observed during life which corresponded to the meningeal hemorrhage that was found at the autopsy.

Dr. W. R. Pryor presented the fundus of a uterus, to which was attached

A TUMOR FORMED BY PYO-SALPINX.

It was removed on the 11th inst. by Dr. H. Marion Sims from a woman who had been suffering from the symptoms belonging to pelvic cellulitis. The growth was sessile, and necessitated amputation at the internal os. Patient died of peritonitis, the result of constriction from old bands, two and a half days after the operation.

There were several pus-cavities in the tumor; one was nearly ready to rupture through the peritoneal covering. The largest cavity was, probably, connected with the Fallopian tube, although it had nothing whatever to do with the mucous lining of the tube. It was a cavity filled with pus. Under proper precautions some of the contents of this cavity were withdrawn for experimental study, with reference to bacteria, and were submitted to Dr. Prudden.

The President said that the cleanliness with which the removal of the fluid was done was proven by the fact that not a single putrefactive bacteria showed itself in any of the cultures that were made. He examined the fluid with special reference to the presence of suppurative bacteria, particularly the staphylococcus pyogenus aureus, but none were found.

Here, then, was

AN ABSCESS WITHOUT SUPPURATIVE BACTERIA.

But the abscess as found was an old one, and probably when acute the suppurative bacteria were present and started it, and then died, the suppuration continuing. The suppuration continued because the cavity was lined throughout with granulation tissue that doubtless originated in an acute process. Cases of this kind would seem to be of practical interest and importance surgically, because of the possibility that such a purulent fluid as this might gain access to the peritoneal cavity without the establishment of a septic inflammation, as, judging from the absence of bacteria, there would be no probability of its doing in this case.

Dr. J. W. Roosevelt presented a specimen of

MALIGNANT STRICTURE OF THE ŒSOPHAGUS WITH CONTRACTION OF THE STOMACH,

removed from the body of a woman, forty-nine years of age. The previous history was that of chronic gastritis. She never vomited blood. About six months before death the pain from which she had suffered disappeared entirely. The constant vomiting of food was almost the only symptom. The small-sized stomach-tube could not be introduced. After that she was rather constipated, this peculiar vomiting continued, and she lost flesh; but, on the whole, the patient did very well. Two weeks before death a small sound could not be passed through the stricture, yet the woman drank fluids and retained them, even as much as a quart at a time, but within half an hour or so the water would be regurgitated, practically unchanged. She lived on milk, however, taking solid food occasionally, which would return within two or three hours after it had been swallowed.

At the autopsy the œsophagus for nearly its entire length was found dilated to about the size of a quart champagne bottle. The stricture consisted of a ring of nodules surrounding the cardia, and the stomach was a little less than six inches in length and two inches in diameter. There were no secondary deposits.

TELANGIECTATIC SARCOMA IN THE MESENTERIC GLANDS—INTRACANALICULAR FIBROMA OF THE MAMMÆ—MYOMA OF THE STOMACH—FIBROMA OF THE UTERUS—FOLLICULAR CYST OF THE OVARY—CHRONIC INTERSTITIAL OÖPHORITIS—HEALED FRACTURE OF THE RIBS—PERFORATING ULCER OF CORNEA WITH PROLAPSE OF IRIS.

Dr. Ira J. Van Gieson presented specimens removed from an adult well-nourished dog.

The two lowermost mammary glands on the right side were replaced by dense, mottled, brownish-white masses, two by three centimetres in diameter. The remaining glands on the right side contained similar masses, but smaller. Contents of thorax normal. On the inner surface of the second, third, fourth, fifth, and sixth ribs there were a series of slightly projecting nodules at the junction of the anterior and the middle thirds. The intestines were normal. The mesenteric glands were swollen and soft. In the stomach there were two dense, white, distinct masses in the muscular coat elevating the mucosa. The liver was fatty in spots. The kidneys and the spleen were normal. In the uterus there was a mass of tissue, attached by a narrow pedicular base to the anterior wall, corresponding to the shape of the uterine cavity and nearly filling it. The left ovary was cystic; the right ovary was shrunken and hard. On both sides the eyelids were glued together. There was pus between the lids and the cornea. There was a perforation of the cornea near the centre on both sides. The brain was normal.

Microscopical examination.—In the mesenteric glands there were a large number of blood-vessels, with thin, delicate walls, surrounded by rather closely packed clusters of small spheroidal cells. The cells nearest the walls of the blood-vessels were cuboidal. Sections of the mammary glands showed a growth of new connective tissue in the ducts, and extending into the acini as pediculated masses. The process was developed to a moderate degree only, and many acini, although slightly dilated, were free from such masses. Scattered through the section were collections of pigment of hematogenous origin. The masses in the stomach consisted of rather loosely packed, smooth muscle-fibres. The tissue in the uterus was composed of fibrous connective tissue covered with epithelium. The left ovary was changed to a fibrous shell enclosing a granular mass of detritus. The right ovary was reduced to a dense mass of connective tissue containing blood-vessels. The nodules on the ribs were caused by the non-apposition of the two ends of the ribs, which have been fractured at these points.

The President remarked that the specimens were especially interesting with reference to the existence of intracanalicular fibroma, which was of infrequent occurrence, and when present was very liable to be mistaken for carcinoma. The case was furthermore interesting on account of the large variety of tumors present.

Dr. Porter remarked that dogs were very liable to sarcoma.

The Society then went into executive session.

OUR LONDON LETTER.

(From our Special Correspondent.)

HOMŒOPATHY IN THEORY AND PRACTICE—THE HUNTERIAN ORATION—MEETING OF THE MEDICAL COUNCIL—THE TEETH AND LOCOMOTOR ATAXY—HYPERPLASTIC SYPHILITIC LARYNGITIS — MALIGNANT GROWTHS OF UPPER JAW—GUY'S HOSPITAL.

LONDON, February 19, 1887.

OPEN war has just been again declared against the homœopaths. The renewal of hostilities is due to a disturbance which has just taken place at the Margaret Street Infirmary for Consumption. This institution is somewhat unique, being more of the nature of a dispensary than of an infirmary, and there is an arrangement whereby the honorary staff visit the patients at their own homes. The fracas has arisen from two of the medical officers practising homœopathically and prescribing homœopathic remedies for the patients. How the other members of the staff should have ascertained the latter fact is somewhat mysterious, unless they either made it their business to spy into the case-books of their colleagues or, perchance, condescended to interview the dispenser in search of information. Neither of these would be in accordance with ordinary professional etiquette, which would lead a physician or surgeon to a public institution to attend to his own patients and not interfere concerning those of his colleagues. The prescribing of homœopathic remedies, however, does not constitute the whole of the offence of the two gentlemen in question. The root and branch of their offending is that they openly call themselves homœopaths, have their names in the "Homœopathic Directory," and that one of them is on the staff of the Homœopathic Hospital. It is difficult to imagine how the latter could ever have got elected on the staff of the Margaret Street Infirmary. Of late years a good deal of tolerance has been exhibited as regards the use of homœopathic remedies. The writings of Ringer and Brunton have, it is said, done much to familiarize the profession with many so-called homœopathic medicines. Of late years, also, many of the disciples of Hahnemann have abandoned the principle of giving infinitesimal doses, but administer as large, or larger, doses as the "allopaths." It is therefore somewhat hard to say where allopathy ends and homœopathy begins, but the tendency has been to restrict the appellation of "homœopath" to those who assume the term and thereby cut themselves off from their brethren as a separate sect. Provided a doctor does not do this, he may, as a rule, prescribe what he likes without exciting odium among the regular practitioners. Unless he openly avows his conversion to their tenets, however, the homœopathists may be down upon him for "stealing their remedies!" They assert that Dr. Ringer, in his "Handbook of Therapeutics," has derived much of his information from homœopathic works, and the same thing is now being said about Dr. Brunton and his recent book. The termination of the Margaret Street episode is slightly amusing. The two homœopathic physicians declining to recede from the position they had taken up, a special general meeting of the governors was called, at which a resolution was moved calling upon them to resign. This was not carried, but an amendment moved by Dr. Dudgeon was successful. The homœopathists therefore remain masters of the field. It is understood that nearly all the remaining members of the staff will resign, and many members of the committee also. The curious spectacle will then be presented of a public medical institution—carried on for years by means of voluntary services rendered by regular practitioners—actually falling into the hands of a few homœopaths to manage according to their own sweet will.

A large audience assembled at the College of Surgeons on Monday to hear Mr. Savory deliver the Hunterian Oration. As was befitting the occasion, the President of the College commenced his oration by eulogizing the memory of Hunter. After referring to the numerous discoveries on which John Hunter's fame rests, Mr. Savory said we must admit that Hunter was neither dexterous as an operating surgeon nor what we should now term a well read man. His greatness was that he was a "philosopher in surgery." His passion for collecting was well known, but he did not collect at hap-hazard merely to fill his shelves. "I believe," said Mr. Savory, "that even the objects found there, which appear most foreign to the subject of his thoughts and work, were not introduced from mere idle fancy, but for the purpose, either at once clearly or dimly seen or at least conceived possible, of throwing light, in some way, upon the great questions of which his mind was full." Mr. Savory claimed for Hunter that he introduced the scientific spirit into surgery, and that from his time downward we could trace his influence upon the scientific study of surgery. To the practice of surgery, principles were what grammar is to language. Men might talk without grammar, and practise surgery with little or no knowledge of its principles; but if unexpected difficulties arose, principles might, hinted the orator, be found useful. As the art of surgery advanced there was a danger of its principles being less studied, and it might be asked whether surgery itself, as a science, might not be in danger from the extension of surgery as an art? Referring to the argument that as surgery advances, and the art grows more extensive, it becomes impracticable for anyone to entertain the whole of it, Mr. Savory referred to the law of the division of labor and the question of specialism. As to the latter, he said he had no word to utter in disparagement of that form of it which consisted in a man first of all studying the principles and practice of surgery as a whole, and then, at length, devoting his attention more especially to the cultivation of some particular department of it. But he denounced that exclusive form of specialism which consisted in the practice of some portion of surgery without adequate attainment in, or continued study of, surgery as a whole. This was a false, as the former was a true, application of the law of the division of labor. Speaking of the rival claims of literature and science, Mr. Savory remarked that each had its place, and it was unfortunate that we should grow indifferent to those branches of knowledge we did not possess, and still worse if, instead of spending our spare time in studying them, we employed it in denouncing or expressing contempt for them.

The General Medical Council met on Tuesday last, their numbers augmented by five, being the number of the members elected by the profession at large. Owing to deaths and resignations, many new faces were seen besides those of the elected members. Being the Jubilee year of the Queen's accession to the throne, the President thought the occasion opportune for giving an address on the progress of medicine during the last fifty years, and his fellow-councillors had no choice but sit and listen to what they probably knew as well as Sir Henry Acland, K.C.B. The inspection of examinations was then discussed and determined on. The workings of the conjoint schemes in England and Ireland were considered at some length.

At this week's meeting of the Pathological Society Dr. Hale White drew attention to the case of a man suffering from locomotor ataxy in whom a tooth had fallen out. Dr. White referred to several similar cases placed on record, in some of which all the teeth had fallen out from the upper jaw. Several speakers corroborated Dr. White's statements. Mr. F. G. Bennett spoke of the falling out of teeth occurring in connection with gout or imperfect nutrition. Mr. Bland Sutton referred to some cases of falling out of the teeth in carnivorous animals suffering from softening of the cord and perforating ulcers. At the same meeting of the society.

Dr. Semon showed (for Dr. Jacob, of Leeds) some photographs of, and microscopical specimens from, a remarkable case of hyperplastic syphilitic laryngitis.

The meeting of the Medical Society, on Monday evening, was wholly occupied in the discussion of two papers on malignant growths of the upper jaw. One, by Dr. Servais, of Antwerp, described two successful cases of removal of the entire upper jaw for cancerous growths involving the two superior maxilla. The other, by Mr. Jessett, gave the history of a case in which Mr. Jessett had removed both upper maxilla for a sarcomatous growth. The operation was successful, and Mr. Jessett brought the patient before the Society to show her present condition five months after the operation.

Some forty-nine thousand pounds have been subscribed toward the fund of one hundred thousand pounds being raised for Guy's Hospital. Another ten thousand pounds has been given conditionally, so there seems now some prospect of the whole sum being collected.

OUR PARIS LETTER.

(From our Special Correspondent.)

THE DEATH OF PROFESSOR BECLARD.

PARIS, February 16, 1887.

I REGRET to report the death of Dr. Béclard, Professor of Physiology and Dean of the Paris Faculty of Medicine, which took place on the 9th inst., after only a few days' illness, at the age of sixty-nine. It is only a little more than a week ago that the learned Professor presided over a banquet offered to Dr. Farabeuf to celebrate his nomination to the Professorship of Anatomy at the Paris Faculty of Medicine. It was on leaving this fête that he was seized with an attack of pneumonia which carried him off so quickly. He was the son of the celebrated Anatomist of that name, whose theories are still respected in the learned world. After having finished his medical studies, he was appointed interne at the Asylum of Charenton where he devoted three years to the study of cerebral diseases. He took his degree in 1842, and three years afterward was promoted to Agrégé of Anatomy and Physiology. In 1851 he began with the works of his father on the elements of general anatomy which, however, had not been completed at his death. He was the author of many important works, all bearing on the subjects of his predilection, viz., anatomy and physiology. A volume entitled: "Notices and Portraits," contains panegyrics of distinguished members deceased, pronounced by him at the annual meetings of the Academy of Medicine in his capacity of Perpetual Secretary. It was thus that he pronounced the eulogies of de Blainville, Delpech, Villermé, Gerdy, Rostan, Velpeau, Trousseau, Louis, Andral, Claude Bernard. As a panegyrist he was scarcely equalled, not only for his erudition but for his impartiality. At the death of Professor Longet in 1871 Dr. Béclard was appointed his successor in the Chair of Physiology but he had already been member of the Academy of Medicine since 1862, when in the same year he was elected Annual Secretary, and his re-election took place every year till 1873, when on the death of Dubois, of Amiens, he was appointed Perpetual Secretary. In 1868 he was designated with Axenfeld, by the Academy of Medicine, to draw out a report on the progress of medicine in France, which was highly appreciated. In 1881, on the resignation, for political reasons, of Professor Vulpian from the Deanship of the Paris Faculty of Medicine, Professor Béclard was nominated his successor. This appointment caused some disaffection among the professors of the Faculty, as it was considered an act of favoritism on the part of Paul Bert, who was then Minister of Public instruction. When, however, these hostile feelings had passed away the most amicable relations existed between them to the day of his death, owing in a measure to his affable and benevolent disposition, although he performed the functions of his office in a most satisfactory manner.

He soon became popular among the professors and students, as he always took a personal interest in the well-being of the latter. He was rather reserved, and avoided as much as possible all public meetings or manifestations, and yet he presented himself as a candidate for the Senate in 1876, but failed. In 1886 he was nominated Commander of the Legion of Honor in recognition of his innumerable services to science and through the latter to humanity. His obsequies took place on Saturday last. The lower part of the great amphitheatre of the Faculty of Medicine was converted into a chapel where the body, which was enclosed in a coffin, was placed on a catafalque which was completely covered with wreaths and flowers. The court-yard and principal entrance were entirely draped with black, which presented a most imposing scene. The funeral service was performed at the Church of Saint Sulpice which, notwithstanding its large size, was so full that many persons had to remain outside. After the service, the procession, composed of more than two thousand persons, continued its course to the cemetery of Père Lachaise, where he was interred in the family vault. The chief mourners were MM. Henry Béclard, his son, and Ferrus, his brother-in-law. The pall was held by MM. Berthelot, Minister of Public Instruction; Liard, Director of Superior Education; Gréard, Vice-Rector of the University of France; Brouardel, Assessor of the Faculty of Medicine; Sappey, President of the Academy of Medicine; Peyron, Director of Public Assistance.

Immediately behind the funeral-car followed the family of the defunct, then came the professors and agrégés of the Faculty of Medicine wearing their official caps and gowns, which were of red, purple, black, yellow, orange, according to the Faculty that they represented, and which had a very picturesque appearance. Next in succession were the delegates of various societies, among whom were some lady-students, twenty-four in number, who bore on their shoulders a magnificent wreath of white camelias, white lilacs, and white hyacinths, which was very much admired. When the procession started from the School of Medicine, the deceased having been a Commander of the Legion of Honor, military honors were paid by a battalion of infantry commanded by a colonel.

At the meeting of the Academy of Medicine yesterday the President announced the death of Professor Béclard, and after having read the oration pronounced by him over the tomb of the deceased Academician the proceedings were at once closed as a mark of respect to the memory of the much esteemed Perpetual Secretary of the Academy.

The lamented death of Professor Béclard causes several vacancies, among which are the Deanship of the Paris Faculty of Medicine and the Perpetual Secretary of the Academy of Medicine. For the former Professor Brouardel would seem naturally designated, as he has been Assessor to the Faculty for many years and is known to possess the qualities requisite for such a position. As regards the Perpetual Secretaryship of the Academy of Medicine it will only be declared vacant at the meeting of next week, and according to the rules of the Academy the election cannot be made till a month after.

FATAL TOBOGGANING ACCIDENT.—The horrible and fatal accident which occurred in Rutland recently, by which a young man lost his life, can hardly fail to dampen a little the prevailing craze for tobogganing. The terrific speed at which the toboggans go when descending the slide makes the lives of those coasting entirely dependent on the security and perfect condition of the icy trough.

ATROPINE IN PULMONARY HEMORRHAGE is recommended by Dr. R. Hausmann, of Meran, in doses of 0.0002 to 0.0003 gramme subcutaneously.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from February 27 to March 5, 1887.

GREENLEAF, CHARLES R., Major and Surgeon. Ordered for duty in the office of the Surgeon-General of the Army. S. O. 41, A. G. O., February 18, 1887.

HUNTINGTON, D. L., Major and Surgeon. Will be relieved from duty in the office of the Surgeon General, to take effect March 1, 1887. S. O. 41, A. G. O., February 18, 1887.

HUNTINGTON, DAVID L., Major and Surgeon. Ordered for duty at San Diego Barracks, Cal., and granted leave of absence for one month, from March 1, 1887. S. O. 45, A. G. O., February 25, 1887.

WHITE, ROBERT H., Captain and Assistant Surgeon. On being relieved by Major Huntington, to proceed to Angel Island, Cal., and report to commanding officer for duty at that post. S. O. 45, A. G. O., February 25, 1887.

GRAY, WILLIAM W., Captain and Assistant Surgeon. Leave of absence for seven days is extended twenty-three days. S. O. 13, Department of Dakota, February 21, 1887.

Medical Items.

RHEUMATISM AND RHEUMATOID AFFECTIONS.—The indefiniteness of our conceptions concerning rheumatism was the theme of an interesting discourse by Professor Immermann at the recent meeting of the German Association of Naturalists and Physicians (*Philadelphia Medical Times*). Immermann regards the morbid process characterized by the classical phenomena of fever, articular inflammation, and peri- or endo-carditis as an infectious disease. A number of other less characteristic affections may be included under the adjective "rheumatic." Among these is acute endocarditis without joint-affections. In these cases a recurrence is sometimes accompanied by a joint-inflammation, showing that the former attack was also rheumatic, although one of the most pathognomonic manifestations was absent. Acute sero-fibrinous pericarditis is also sometimes seen, in which, in spite of the absence of other symptoms, rheumatism may be diagnosticated. The presence of valvular lesions of the left heart in such cases, indicating preceding endocardial inflammation, is an almost certain evidence of the rheumatic nature of the attack. Certain forms of what Immermann terms *masked rheumatism* may also be often recognized. One of the most frequent of these is neuralgia, most frequent in the trifacial and sciatic nerves. They may be accompanied or not by fever. They occur in persons who have previously suffered from classical rheumatic attacks, or are accompanied by endocarditis or followed by joint-inflammation. A peculiar form of masked rheumatism is the spastic. Contraction or stiffness of muscles, especially of those in the area of distribution of the spinal accessory nerve, comes on suddenly, accompanied by fever and pain in the affected muscles. The stiffness of the neck-muscles may simulate an attack of cerebro-spinal meningitis. The absence of an epidemic of the latter disease and the prevalence of rheumatism at the time will help in making a diagnosis. Salicyl compounds and antipyrin are specific in their influence upon true rheumatism, and may be used as diagnostic aids, just as the iodides are sometimes relied upon to make a diagnosis of syphilis. Gonorrhœal and scarlatinal joint-affections, purpura with joint-complications, the so-called *peliosis* or *purpura rheumatica*, the articular affections in individuals suffering from bronchiectasis, rheumatic tetanus, Landry's paralysis, acute anterior poliomyelitis of adults, sporadic acute polyneuritis, and beriberi, may be for the present classed as *rheumatoid* affections, in order to distinguish them from true rheumatism, from which they differ in clinical history as well as in treatment. The painful affections resulting from "taking cold" should be designated, as suggested by Erb, as "refrigeratory," and not as "rheumatic."

SOME EXPERIMENTS WITH TUBERCLE BACILLI.—Dr. de Toma arrives at the following conclusions from a series of experiments made to determine certain points concerning the tubercle bacillus. The first question was how long dried tuberculous sputum can retain its specific virulence. He says that the sputum may remain virulent for nine or ten months if thoroughly dried and kept free from moisture at a temperature of 77° F. When transplanted to blood-serum such sputum will result in fresh virulent cultures of the tubercle bacillus. In a temperature of from 86° to 95° F. the sputum loses some of its specific activity in about two months, and becomes inert when kept for a month in a temperature of 122° F., or for an hour in one of 176° to 212° F. The second question was what are the means of entrance of the tubercular infection into the organism, and especially whether the specific bacillus can be introduced by inhalation. He finds that the artificial inhalation of pulverized tuberculous sputum may, indeed, cause a tubercular infection, but only under certain circumstances, when the system is weakened by fasting or long confinement, or when there is a solution of continuity in the mucous membrane of some portion of the respiratory tract. The last point to determine was the paths by which the bacilli were transported in the body after having once gained admittance. The author says that the bacilli begin to grow and increase in number at the point of inoculation, and are thence carried to other parts in the lymph-current. Very probably, however, the wandering cells, which take up the bacilli and their spores, play a not unimportant rôle in the generalization of tuberculosis. The bacilli are found most plentifully in the young tubercles, and their number decreases directly in proportion to the age of the latter.—*Allgemeine Medicinische Central-Zeitung*, October 2, 1886.

SYPHILITIC INFECTION BY THE RAZOR.—Prof. Fleischer has recently reported a case occurring in his practice where a man had contracted syphilis from an infected razor in one of the best hair-dressing establishments in Kief. The local medical society thereupon decided to call the attention of the sanitary authority to the subject, in the hope that it would make regulations to obviate a repetition of such an occurrence. Another case of the same kind has also been published lately. It was that of a soldier, who had been infected with a primary sore of the chin from being shaved in a public shaving establishment in Tiflis. This case was shown to the Caucasian Medical Society by Dr. Chudnovski.—*The Lancet.*

THE HAIRS OF OUR HEAD NUMBERED.—A German inquirer has, it is stated, taken four heads of hair, of equal weight, and then proceeded to count the individual hairs. One (red) was found to contain 90,000 hairs; another (black), 108,000; a third (brown), had 109,000; and the fourth (blonde), 140,000.

ARE LUPUS AND TUBERCULOSIS IDENTICAL?—The view establishing the identity of lupus and tuberculosis has been accepted by many pathologists. Dr. Schwimmer, of Budapesth, at the recent Berlin Congress, strongly opposed it, mainly for clinical reasons. He said that the affection known as tuberculosis of the skin is a very rare one, while lupus occurs frequently (*The Therapeutic Gazette*). Among 2,400 patients, Schwimmer found 90 cases of lupus, but only 5 cases of pronounced tuberculosis of the skin. The clinical diagnosis in the latter affection is based on the bacterial

proofs. In all of these 5 cases there was a rapid disintegration of the nodes. Besides, it is found that this affection invariably proceeds from the mucous membranes; while lupus appears on the epidermis, away from the mucous membranes, which, as a rule, this affection does not implicate. True, there have been observed cases of lupus on mucous membranes, but their number was very limited, and, besides, it is questionable whether the diagnosis was a correct one. Then, the impression produced by the lupoid affection upon the general system is also to be taken into consideration. Tuberculosis, on the other hand, is a general disease; therefore it is not remarkable that lupoid patients sometimes become also tubercular. Hence we can look upon tuberculosis in a lupoid patient as a matter of mere coincidence. The author detailed two cases in which the clinical history went far in showing that the skin-affection present was lupus, and that the coexisting tuberculosis was an additional acquisition, having no relation with the lupus. Among 90 lupus patients, Schwimmer found sixty-eight per cent. constitutionally untainted; in fifteen per cent. only he found a hereditary element. These facts speak against any etiological relation of the two diseases. Besides, it is at least singular that this relation, if actually existing, should not have been observed sooner. Schwimmer knows 33 cases of lupus, of which 15 have for the last twelve years been under his observation, and of which not a single case showed the slightest symptoms of tuberculosis. As a last support of his view Schwimmer advances the bacterial fact entering into the question. Many observers allege that in lupus but few, and but rarely, tubercle-bacilli are found. It is to be remembered that the tubercle-bacilli have a great resemblance to those found in lepra, both as far as form and chemical reaction go. Schwimmer shares the view of Professor Babes, that the differentiation of the single bacillus is a matter of utmost difficulty. Hence Schwimmer cannot be induced to look upon lupus as an affection either identical with or predisposing to tuberculosis. In the discussion which followed, Doutrelepont, Lassar, Lewinski, and Lewin, all opposed Schwimmer. Kaposi, of Vienna, alone upheld the latter's view. His remarks were introduced by what appeared an especial hit against the bacteriological school. "If the gentlemen," said the Viennese authority, "have microscopical evidences of the identity of lupus and tuberculosis, we cannot help that. But, above all, the clinical features of an affection must be considered; for we are practitioners, and not biologists. Otherwise we will be led toward false diagnoses."

Peroxide of Hydrogen in Pertussis.—Dr. B. W. Richardson uses the following formula, and thinks there is nothing quite so good as it in whooping-cough:

℞. Hydrogen peroxide (ten per cent.).. ℥ vi.
Glycerini..... ʒ ss.
Aq. destillat.....ad ʒ iij.
Sig.— ʒ ss. at a dose.

The Discoverer of Saccharin.—Professor Ira Remsen, of the Johns Hopkins Laboratory, writes to the *New York Times* to say that saccharin was discovered by himself, or rather by Fahlberg while working under his directions and with him. Professor Remsen says: "In all his statements regarding the substance in question he (Fahlberg) strives to make the impression that the discovery is his, and in most references to it in print he is given sole credit. I think it is time that I protest in the interest of truth and justice. Fahlberg carried out my directions and deserves credit for this, and for this alone. He did not make the discovery and would never have made it if he had been left to his own resources. The sulphinide saccharin belongs to an entirely new class of compounds which are now under investigation in this laboratory. Some of the other members of the class are sweet, while some are intensely bitter. One is sweet, and bitter-sweet when applied to the tip of the tongue, and bitter when applied to the base of the tongue. These substances have nothing in common with sugar, except the sweet taste. Finally, other sweet substances beside the sulphinides have been made from coal-tar and have long been known, but the world has not been excited over them, and there is, in my opinion, no occasion for getting excited over this latest example of the kind."

Effect of Iron on the Composition of Milk.—Dr. Mendes de Léon has made a number of researches and observations on the supposed effect of taking iron on the composition of the milk secreted. He finds that milk always contains a minute quantity of iron, which differs in different species of animals, cow's milk, for example, being richer in iron than human milk. He gave various preparations of iron to a healthy multipara and analysed the milk, but was unable to detect any increase in the iron it contained, so that it would appear that iron given to the mother does not act on the child by passing into its system, but that it may act by improving the general condition of the mother, and thus causing her to secrete better milk.

The Diet of Centenarians.—A writer on this topic holds in a contemporary that "the rules of life laid down by Cornaro are probably perfect," and he intimates that, in his opinion, "twelve ounces of solid food and sixteen ounces of liquid appear to be the maximum requirements of age." The solids ought, he thinks, to be made up of one-third animal food, chiefly flesh, and two-thirds vegetable nourishment. He dislikes fruit and fish, and says that salt and sugar should only be used sparingly. He also deprecates the too copious use of milk as well as of drugs, and after adding that industry of some kind should be practised, he gravely points out the valuable medicinal properties of port wine. The latter is certainly more suited to advanced life than is almost any other form of stimulant.

Ethereal Oxygen.—Dr. Richardson writes in *The Æsclepiad:* "Ethereal oxygen is a compound I have recently invented for inhalation. I place in a Wolff's bottle, with an inhaling mouthpiece attached to one neck, two ounces or more of ozonic ether, the ethereal solution of peroxide of hydrogen. To this I add, gradually, solution of permanganate of potassa—eight grains to one ounce of water—by the other neck of the bottle, and then cork that neck. As the fluids commingle, oxygen gas and ether vapor are given off freely, and can be inhaled from the mouthpiece. The compound of gas and vapor, anæsthetic, antispasmodic, and respirating, is applicable to a large class of cases of disease, such as pertussis, asthma, and phthisis. I doubt if I ever added anything more useful to practical therapeutics than ethereal oxygen."

M. Greville and the First Use of Chloroform.—"I went yesterday (1848)," says Mr. Greville, in his recently published journal of "The Reign of Queen Victoria," vol. iii., p. 110, "to St. George's Hospital, to see the chloroform tried. A boy, aged two years and a half, was cut for a stone. He was put to sleep in a minute, the stone was so large and the bladder so contracted, the operator could not get hold of it, and the operation lasted above twenty minutes. . . . A curious example was shown of, what is called, the *etiquette* of the profession. The operator could not extract the stone, so at last handed the instrument to Keate, who got hold of the stone; thereupon the first surgeon begged to have the forceps back that he might draw it out, and it was transferred to him; but, in taking it he let go the stone, and the whole thing had to be done over again. It was accomplished, but not, of course, without increasing the local inflammation and endangering the life of the child. I asked Keate why, when he had got hold of the stone he did not draw it out. He said the other man's 'dignity' would have been hurt if he had not been allowed to complete what he had begun."

The Medical Record

A Weekly Journal of Medicine and Surgery

Vol. 31, No. 12 NEW YORK, MARCH 19, 1887 Whole No. 854

Original Articles.

REPORT OF ONE HUNDRED AND TWENTY-FIVE LAPAROTOMIES, WITH OBSERVATIONS ON THE USE OF HOT WATER WITHIN THE PERITONEAL CAVITY DURING AND AFTER LAPAROTOMY TO PREVENT SHOCK — TREATMENT OF SEPTIC PERITONITIS AND INTESTINAL OBSTRUCTION BY THE USE OF PURGATIVES, ETC.[1]

BY W. GILL WYLIE, M.D.,

NEW YORK.

ABDOMINAL surgery has made rapid progress in the past ten years, and it has excited much interest. It has for some time past been the popular topic at society meetings, and much space in medical journals has been given up to articles on abdominal surgery.

To those not particularly interested in special surgery this has become rather tiresome, and many conservative advocates have arisen and entertained us with lengthy polemical articles based upon their opinions rather than on actual experience. Some of these articles are written in a most melancholy and dolefully prophetic strain, and I have no doubt but that they make sweet harmony on the sympathetic chords in the most conservative of conservatives and the most unfortunate of unsuccessful operators; but in medicine, as in all other things, human progress and success meets with opposition.

All must admit that progress and success come from enthusiastic and persistent devotion to one subject. When success forces the subject to become the topic of the day, the fashion, it is pretty certain to be carried too far, and mistakes and excesses will be committed by the rash and incompetent; but this is only human nature, and should not result in condemning what is good, as well as what is bad in the work. After all, success is the crucial test.

At the risk of being tiresome and more or less personal, I will give a short summary of my work in abdominal surgery, and touch briefly on one or two practical points.

Previous to November, 1882, except as an assistant to the late Dr. J. Marion Sims, I had done very little work in abdominal surgery, having operated only seven times—six ovariotomies and one Batty's operation for removal of the ovaries for local pain in a bedridden patient. I lost one of the ovariotomies and the Batty from septicæmia; the others recovered.

November 19, 1882, I did my first laparotomy in Bellevue Hospital. Since then I have kept a record of all cases. I have never, in a single instance, refused to operate where I thought there was a chance of saving or even prolonging life. On the contrary, I have undertaken several cases that were hopeless, and now, with my increased experience, would probably not try an operation in similar cases.

Of the 125 laparotomies done since November 18, 1882: In 1882, 2 cases; in 1883, 7 cases; in 1884, 14 cases; in 1885, 47 cases; and in 1886, 55 cases—or 125 cases in all. Of these, 12 died; but 3 of these 12 were suprapubic hysterectomies, and 1 a very bad case of general suppurative peritonitis. Excluding the hysterectomies and general peritonitis, I have 116 with 8 deaths, or a death-rate a little less than seven per cent. The 125 cases can be classified as follows:

Seventy-four removals of uterine appendages, 5 deaths. Nearly fifty per cent. of these were genuine cases of pyosalpinx, many of them complicated by pelvic abscesses. All five of the deaths were complicated cases. In the last 37 cases only 1 died.

Twenty-six ovariotomies, 3 deaths. The three were complicated cases—one gangrenous, one suppurating, and the third had been tapped eleven times, and died of exhaustion on the fourth day.

Seven suprapubic hysterectomies, 3 deaths. One that died was a cancer case; another was a fibrocystic myoma that weighed fifty pounds; in the third two large myomata had to be enucleated from the broad ligaments. All three died of shock.

Eighteen miscellaneous laparotomies, 1 death. One nephorectomy (suppurating), 1 perityphlitis, 8 ventral herniæ, 2 intestinal obstruction, 1 extra-uterine pregnancy, 2 permanent drainage of tubercular peritonitis, 1 exploratory for cancer, omentum, etc.; 1 for gall-stones, 1 for general acute suppurative peritonitis.

So far I have never yet lost a simple case. All of those that died were complicated cases; nor have I had any accidents from hemorrhage. Although five of the twelve deaths were from shock, none died on the table. Almost exactly one-half of these cases were done in Bellevue Hospital, some of them in the general ward; and of 64, 7 died—2 of these were hysterectomies, 1 acute general peritonitis; excluding these, there were 4 deaths in 61 hospital cases, or about seven per cent.

Much of my success was due to the excellent assistance that I have had from the different house-physicians in Bellevue, and to my three regular assistants that I have had for the past two years—Dr. Crandall, Dr. R. A. Simpson, and Dr. R. H. Wylie.

An examination of the tabulated cases shows a steady improvement.

In 1883,	5	cases	of	removal	of	appendages with 1 death.
" 1884,	10	"	"	"	"	" 1 "
" 1885,	23	"	"	"	"	" 2 deaths.
" 1886,	36	"	"	"	"	" 1 death.

with no deaths in the last 27 cases.

Thirty-six cases in one year may seem large, but most of these were sent to me by other doctors for operation. Unless the case is easily made out as one in which an operation is the only way of effecting a cure, I do not undertake the operation without giving the patient the benefit of the doubt, by keeping her under observation and local treatment for a sufficient time to give a fair test of other methods of treatment.

Repeated attacks of local peritonitis, or a constant burning pain over the appendage, which is at times rendered rather worse than better by any form of local treatment, is perhaps the most reliable indication that removal is the only way of giving relief.

This report does not include cases operated on this year (1887).

The first fourteen cases of Table I. were fully reported in my paper on "Disease of the Fallopian Tubes," in THE MEDICAL RECORD, January 24 and February 7, 1885.

[1] Read before the Medical Society of the State of New York, February 2, 1887.

TABLE I.

No. of case.	Date of operation.	Age.	Married or single.	Number of children.	Number of abortions.	Number of tappings.	Diagnosis.	Operation.	Drainage.	Results.	Remarks.
1. Hospital	May 26, 1883.	32	M.	2	2	.	Pyosalpinx.	. .		Recovered.	
2. Hospital	June 25, 1883.	25	M.	..	.	.	Pyosalpinx.	. .	.	Recovered.	
3. Hospital	October 28, 1883.	27	M.	2	..	.	Catarrhal s.	. .	..	Recovered.	
4. Hospital	December 8, 1883.	31	M.	2			Pyosalpinx.	. .		Died.	
5. Private	December 3, 1883.	23	S.	..			Catarrhal s.	. .		Recovered.	
6. Hospital	November 17, 1883.	29	M.	1	.	.	Hydrosalpinx.	. .	..	Recovered.	
7. Hospital	March 3, 1884.	28	M.	..			Hydrosalpinx.	. .	..	Recovered.	
8. Private	March 13, 1884.	27	M.	..	1	..	Catarrhal s.	. .	..	Recovered.	
9. Hospital	March 20, 1884.	27	M.	..		..	Pyosalpinx.	. .	..	Died.	
10. Private	May 1, 1884.	25	M.	..	.	.	Pyosalpinx.	. .	..	Recovered.	
11. Hospital	October 9, 1884.	30	M.	1	.	.	Pyosalpinx.	. .	..	Recovered.	
12. Private	October 20, 1884	28	S.	..			Catarrhal s.	. .	..	Recovered.	
13. Hospital	November 29, 1884.	26	M.	1		..	Pyosalpinx.	. .	..	Recovered.	
14. Hospital	December 8, 1884.	31	M.	3	2	.	Pyosalpinx.	. .	..	Recovered.	
15. Hospital	January 19, 1885.	28	M.	7	4	.	Catarrhal s. and degenerated ovaries.	. .	..	Recovered.	
16. Hospital	February 2, 1885.	35	S.	..	..		Catarrhal s. and cystic ovaries.	. .	..	Recovered.	
17. Hospital	February 28, 1885.	29	W.	3	3		Pyosalpinx.	. .	..	Recovered.	
18. Hospital	April 2, 1885.	50	S.	..	.	.	Catarrhal s. and atrophied ovaries.	. .	..	Recovered.	
19. Hospital	April 6, 1885.	27	M.	2	..	..	Catarrhal s. and cystic ovaries.	. .	.	Recovered.	
20. Hospital	May 1, 1885.	23	S.	..	.	..	Pyosalpinx ovaritis; abscess.	. .		Died.	
21. Private	May 9, 1885.	50	M.		..	..	Hypertrophied tube; fibro-cystic ovary.			Recovered.	
22. Private	May 17, 1885.	25	S.	..	..	..	Catarrhal s.; fimbriæ adherent.	.		Recovered.	
23. Hospital	May 20, 1885.	21	S.	..	..	..	Catarrhal s.; left ovary cystic.			Recovered.	
24. Hospital	June 4, 1885.	29	M.	..	4	..	Catarrhal s.; fimbriæ adherent; small ovarian cyst.			Recovered.	
25. Hospital	June 17, 1885.	26	M.	1	1	..	Catarrhal s. and occluded tubes.	..	..	..	..
26. Private	July 2, 1885.	38	M.	1		..	Submucous fibroid.	Uterine appendages removed.	No.	Recovered.	Three weeks after operation the fibroid sloughed, and was removed per vaginam with forceps.
27. Private	October 5, 1885.	27	S.	..	.		Prolapsed and adherent left ovary.	Only left ovary removed.	No.	Recovered.	Constant pain, practically bedridden; under constant treatment for six years.
28. Hospital	October 11, 1885.	32	M.	3	1		Pyosalpinx ovaritis.	Removal of appendages complete.	Yes.	Recovered.	Adhesions; tubes occluded and enlarged.
29. Hospital	October 19, 1885.	41	W.	1	..		Pyosalpinx ovaritis.	Removal of appendages complete.	Yes.	Recovered.	Adhesions; tubes occluded and enlarged.
30. Hospital	October 28, 1885.	21	S.	..	.		Cystic degeneration ovaritis.	Complete removal of appendages.	No.	Recovered.	Local pain; inability to work; frequent epileptiform convulsions.
31. Private	November 4, 1885.	43	W.	2	..	..	Had been treated for extra-uterine fœtation.	Complete removal of appendages.	Yes.	Recovered.	Right tube contained three pints of fluid; left, obliterated; no signs of fœtus.
32. Hospital	November 7, 1885.	17	S.	..	..	..	Cystic degeneration of ovaries.	Removal of appendages complete.	No.	Recovered.	Well-marked hystero-epilepsy.
33. Hospital	November 12, 1885.	22	M.	1	1	..	Pyosalpinx; ovaritis; pelvic abscess.	Removal of appendages complete and sac of abscess.	Yes.	Recovered.	Abscess size of orange.
34. Private	November 16, 1885.	23	M.	..	..		Cystic degeneration; ovary as large as a lemon.	Removal of appendages complete.	Yes.	Died.	Ovarian hæmatocele as large as an orange; hystero-epilepsy of seven years; mind affected; died a raving maniac on fourth day after operation.
35. Private	November 28, 1885.	27	M.	1	..	..	Pyosalpinx.	Removal of appendages complete.	Yes.	Recovered.	Tubes indurated, occluded, and adherent.
36. Hospital	December 10, 1885.	32	M.	..	1		Ovaritis.	Removal of appendages complete.	No.	Recovered.	Left ovary enlarged and adherent; tubes adherent, not occluded.
37. Private	December 23, 1885.	26	S.	..	1	..	Fibroid degeneration of ovaries.	Removal of appendages complete.	No.	Recovered.	Ovaries double their normal size; adhesions; intense local pain; fear of insanity.
38. Private	January 28, 1886.	39	M.	3			Pyosalpinx; ovaritis; pelvic abscess.	Removal of appendages complete.	Yes.	Recovered.	Pus, nine ounces—three in the right and six in the left; extensive adhesions.
39. Hospital	April 3, 1886.	22	M.	1		..	Pyosalpinx; ovaritis.	Removal of appendages complete.	Yes.	Recovered.	Large, adherent, and occluded tubes.
40. Private	April 7, 1886.	27	M.	..	1	.	Pyosalpinx; ovaritis.	Removal of appendages complete.	Yes.	Recovered.	Ovaries as large as lemon; tubes adherent and occluded.
41. Private	April 10, 1886.	28	S.		1		Cystic degeneration of ovaries.	Removal of appendages complete.	No.	Recovered.	Tubes normal; ovaries enlarged; local pain well marked; hystero-epilepsy.
42. Hospital	April 19, 1886.	32	S.	..	.	.	Uterine fibroids.	Appendages removed.	No.	Recovered.	There were several fibroids which were very painful.
43. Private	April 21, 1886.	27	M.	.	1	.	Pyosalpinx; ovaritis.	Removal of appendages complete.	Yes.	Recovered.	Ovaries size of orange; tubes, large as wrist, adherent and occluded.
44. Private	May 3, 1886.	30	S.	..	..		Prolapsed and adherent left ovary.	Only left ovary removed.	No.	Recovered.	Intense pain over left ovary; bedridden.
45. Hospital	May 5, 1886.	22	S.	..	..		Atrophy of left ovary; right, normal.	Only left ovary removed.	No.	Recovered.	Left ovary the size of a bean; severe and constant local pain; bedridden.
46. Hospital	May 10, 1886.	28	M.	..	..	..	Pyosalpinx; ovaritis.	Removal of appendages complete.	Yes.	Recovered.	Tubes adherent and occluded.

TABLE I.—*Continued.*

No. of case.	Date of operation.	Age.	Married or single.	Number of children.	Number of abortions.	Number of tappings.	Diagnosis.	Operation.	Drainage.	Results.	Remarks.
47. Private.....	May 12, 1886.	33	M.	..	..	..	Pyosalpinx; ovaritis.	Removal of appendages complete.	Yes.	Died.	Quart of bloody fluid in two sacs; dense adhesion; marked indications of intestinal obstruction.
48. Hospital.....	May 20, 1886.	30	S.	1	..	..	Prolapsed, slightly adherent ovaries.	Laparotomy; appendages loosened and returned.	No.	Recovered.	Tubes and ovaries apparently normal; were returned.
49. Hospital.....	May 20, 1886.	33	M.	..	1	..	Pyosalpinx; ovaritis.	Removal of appendages complete.	Yes.	Recovered.	Tubes size of thumb, adherent and occluded.
50. Hospital.....	May 26, 1886.	45	S.	..	..	..	Pyosalpinx; ovaritis.	Removal of appendages complete.	Yes.	Recovered.	Tubes as large as thumb, adherent and occluded.
51. Private.....	May 27, 1886.	34	M.	..	..	.	Hydrosalpinx.	Removal of appendages complete.	Yes.	Recovered.	One tube size of orange; both adherent and occluded.
52. Private.....	May 29, 1886.	33	S.	..	..	..	Typical cystic degeneration of ovaries.	Complete removal of appendages.	No.	Recovered.	Ovaries were bags of small cysts; constant local pain: confirmed invalid; fifteen years under treatment.
53. Hospital.....	June 3, 1886.	45	M.	9	3	.	Prolapsed, adherent ovaries.	Complete removal of appendages.	No.	Recovered.	Constant, intense pain; unable to walk or work.
54. Hospital.....	June 3, 1886.	23	M.	..	1	..	Pyosalpinx; ovaritis; pelvic abscess.	Removal of appendages complete.	Yes.	Recovered.	Tubes adherent and occluded; left ovary centre of a pelvic abscess.
55. Private.....	June 3, 1886.	33	S.	..	..	..	Prolapsed, adherent ovaries.	Complete removal of appendages.	No.	Recovered.	Local pain, confirmed invalid for eight years; six years in bed.
56. Private.....	June 12, 1886.	21	S.	.	..	..	Cystic degeneration; ovaries prolapsed and enlarged.	Removal of appendages complete.	No.	Recovered.	Local pain; bedridden for three years; hystero-epilepsy.
57. Private.....	June 19, 1886.	32	M.	..	5	..	Pyosalpinx; degenerated ovaries.	Removal of appendages complete.	Yes.	Recovered.	Cysts held a quart of dirty fluid; tubes occluded and distended.
58. Private.....	October 4, 1886.	21	S.	..	..	.	Hystero-epilepsy; prolapse of ovaries.	Removal of tubes, ovaries, and pampiniform plexus.	No.	Recovered; no temperature.	Four months after operation had no menstruation nor convulsion.
59. Hospital.....	October 4, 1886.	30	M.	1	..	..	Salpingitis; ovaritis; pelvic abscess; pyosalpinx.	Removal of appendages and sac of abscess.	Yes.	Recovered; highest temperature 100°.	History of severe local peritonitis; abscess of several ounces, involving tube and ovary.
60. Private.....	October 13, 1886.	23	S.	..	..	..	Cystic ovaries; intense local pain; bedridden; invalid for years.	Removal of tubes, ovaries, and pampiniform plexus.	No.	Recovered; no temperature.	Three months after operation much improved; up and about; no pain.
61. Hospital.....	October 16, 1886.	25	M.	2	5	..	Salpingitis; ovaritis; pyosalpinx.	Removal of appendages.	Yes.	Recovered; highest temperature 99⅖°.	History of local peritonitis: tubes indurated and size of thumb.
62. Hospital.....	October 21, 1886.	32	M.	1	..	..	Enlarged and prolapsed ovaries, size of a lemon.	Removal of appendages; small ovarian tumor.	No.	Recovered; highest temperature 101°.	Three years an invalid; severe pelvic pain.
63. Private.....	November 4, 1886.	30	M.	1	..	..	Pelvic abscess and pelvic tumor, part of ovary.	Removal of abscess sac and cystic ovary.	Yes.	Recovery complete; no temperature.	Abscess due to suppuration about pedicle of a former operation; part of ovary was left in first operation, three months ago.
64. Hospital.....	November 15, 1886.	27	W.	..	..	..	Disease of tubes and ovaries; hydrosalpinx.	Removal of appendages.	No.	Recovered; highest temperature 99¾°.	Both tubes distended, size of wrists, with clear fluid.
65. Hospital	November 15, 1886.	31	S.	..	..	1	Pyosalpinx; pelvic abscess, double.	Removal of appendages and sack of pelvic abscess.	Yes.	Recovered; highest temperature 103⅕°. eighth day.	One abscess, involving left tube and ovary, held six ounces pus; right side three ounces.
66. Private.....	November 18, 1886.	31	S.	..	..	..	Ovarian neuralgia.	Removal of right ovary and tube; left tube had been previously removed.	No.	Recovered; no temperature.	Six months ago left ovary was removed for neuralgia, causing complete invalidism; pain came on in right two months later; fibroids in uterus and in the ovaries found on last operation; patient completely recovered.
67. Private.....	November 21, 1886.	33	M.	..	..	..	Fibroma of uterus; intense local pain.	Removal of tubes, ovaries, and pampiniform plexus.	No.	Recovered; no temperature.	Had been under constant treatment eight years; wore pessary most of the time.
68. Private.....	November 27, 1886.	25	M.	..	..	..	Salpingitis and ovaritis; pyosalpinx.	Removal of both tubes and ovaries.	Yes.	Recovered; highest temperature 101°.	Two attacks of peritonitis, last due to stem pessary; complete invalid.
69. Hospital.....	November 29, 1886.	26	M.	..	..	.	Pyosalpinx.	Removal of appendages.	Yes.	Recovered; highest temperature 99¾°.	Extensive adhesions to intestines, etc.; enlarged and hardened tubes.
70. Private.....	December 6, 1886.	31	S.	..	..	..	Prolapse of both ovaries; intense pain for years.	Removal of tubes, ovaries, and pampiniform plexus.	No.	Recovered; no temperature.	Small fibromatas on uterus and ovaries; the latter large and very hard.
71. Private.....	December 8, 1886.	22	S.	..	.	1	Pelvic abscess and fibroid tumor.	Abdominal incision.	Yes.	Recovered; highest temperature 100°.	Two more ounces of pus evacuated; three weeks later, large abscess was drained by vagina.
72. Private.....	December 11, 1886.	..	M.	..	..	..	Salpingitis; ovaritis; pyosalpinx.	Removal of both tubes and ovaries.	Yes.	Recovered; highest temperature 100½°.	Several attacks of peritonitis; bedridden for five years; history of gonorrhœa.
73. Hospital.....	December 13, 1886.	35	W.	..	..	..	Pyosalpinx; fibroids.	Removal of appendages and a small fibroid.	Yes.	Recovered.	Tubes enlarged, filled with pus, very adherent; small fibroid had to be removed to secure pedicle.
74. Private.....	December 18, 1886.	50	S.	..	..	..	Fibroma of uterus; intense pain; bedridden; menorrhagia.	Removal of tubes, ovaries, and pampiniform plexus.	No.	Recovered; no temperature.	Invalid for many years, unable to go about; intense pain, treated for peritonitis.

TABLE II.—*Ovariotomies.*

No. of case.	Date of operation.	Age.	Married or single.	Number of children.	Number of abortions.	Number of tappings.	Diagnosis.	Operation.	Drainage.	Results.	Remarks.
1. Bellevue Hospital.	November, 1882.	21	S.	..	..	..	Adherent ovarian cyst.	Ovariotomy.	Yes.	Recovered.	Genuine fibro-cyst of ovary, size of a man's head; every part of the tumor firmly adherent.
2. Private	December 18, 1882.	32	W.	1	1	..	Multilocular ovarian tumor.	Ovariotomy.	No.	Recovered.	Size of full term; double multilocular ovarian tumors.
3. Bellevue Hospital.	April 10, 1884	33	M.	..	..		Ovarian cyst; suppurating.	Removal of part of cyst and drainage.	Yes.	Recovered.	Large suppurative cyst; very adherent.
4. Bellevue Hospital.	May 22, 1884.	23	M.	1	1	1	Parovariancyst.	Laparotomy; partial removal.	Yes.	Recovered.	Supposed to have been cyst of broad ligament and was tapped; it refilled.
5. Private	November 19, 1884.	32	M.	2		.	Pelvic hæmatocele and ovarian tumor.	Ovariotomy and removal of hæmatocele.	Yes.	Recovered.	Hæmatocele of two years' standing; rapid development of ovarian cyst, twenty pounds.
6. Bellevue Hospital.	December 6, 1884.	62	W.	7	2		Ovarian cyst.	Laparotomy enucleated.	Yes.	Recovered.	Parovarian pedicle of whole width of broad ligament; extensive adhesions.
7. Bellevue Hospital.	February 9, 1885.	17	S.		..	1	Suppurating ovarian tumor.	Ovariotomy.	Yes.	Recovered.	Hectic fever from suppurative peritonitis; case complicated by pelvic abscess; no pedicle could be secured; stump secured into external wound.
8. Bellevue Hospital.	March 28, 1885.	30	M.		2		Suppurating pelvic cyst.	Ovariotomy.	Yes.	Recovered.	About two quarts of albuminous fluid and pus were evacuated.
9. Private	April 11, 1885.	50	M.	6	.	8	Multilocular ovarian cyst.	Ovariotomy.	Yes.	Recovered.	Some adhesion; patient weak, but recovered without a bad symptom.
10. Private	May 10, 1885.	40	M.			..	Ovarian tumor?	Ovariotomy.	Yes.	Recovered.	Fibro-cystic tumor of left ovary, with very thick walls and attached uterus; large stump was secured externally.
11. Bellevue Hospital.	May 26, 1885.	24	M.	..	4	..	Ovarian cyst?	Ovariotomy.	No.	Recovered.	Small simple cyst of left ovary.
12. Private	June 6, 1885.	26	M.	1	..		Ovarian tumor.	Ovariotomy.	No.	Recovered.	Twenty-five pounds; no adhesion.
13. Private	September 26, 1885.	41	W.	1	..	..	Ovarian tumor.	Ovariotomy.	No.	Recovered.	Papillomatous lining; weight sixteen pounds.
14. Hospital	October 1, 1885.	62	W.		..	..	Simple ovarian tumor.	Ovariotomy.	No.	Recovered.	Weight twenty pounds.
15. Private	November 25, 1885.	55	M.		.	6	Multilocular ovarian tumor.	Ovariotomy.	Yes.	Recovered.	Weight forty pounds; unable to sit up; very feeble; general anasarca; pulse 125 to 140.
16. Private	December 18, 1885.	30	M.	1			Gangrenous dermoid cyst.	Ovariotomy.	Yes.	Died: 26 hours, of shock.	Cyst firmly adherent, and when opened fetid gas freely escaped; patient feeble with hectic fever.
17. Hospital ...	February 15, 1886.	36	M.	3	3	10	Multilocular ovarian tumor.	Ovariotomy.	Yes.	Recovered.	Weight thirty pounds; extensive adhesion; patient very feeble, and nearly died from exhaustion.
18. Hospital	March 28, 1886.	30	M.	1		..	Suppurating ovarian cyst.	Ovariotomy.	Yes.	Recovered.	Weight six pounds.
19. Hospital	April 24, 1886.	64	M.	5		11	Multilocular ovarian cyst.	Ovariotomy.	Yes.	Died of exhaustion 5th day.	Weight forty-three pounds; extensive adhesion; patient very feeble, cannot lie down, and too weak to sit up.
20. Private	April 26, 1886.	42	M.	3	.	.	Multilocular ovarian cyst.	Ovariotomy.	No.	Recovered.	Weight sixteen pounds.
21. Private	May 8, 1886.	30	M.	2			Fibro-cystic tumor of uterus.	Ovariotomy; removal of part of tumors.	Yes.	Recovered.	Large cyst filled with papilloma, and a large adherent fibro-cyst of the uterus; one on either side of pelvis.
22. Bellevue Hospital.	October 27, 1886.	49	S.	..		..	Multiple cysts and peritonitis.	Six cysts, size of oranges, removed.	Yes.	Recovered.	Two distinct attacks of peritonitis; chronic peritonitis; character of thin walled cysts doubtful.
23. Private	October 29, 1886.	53	W.	..		4	Multilocular ovarian tumor.	Ovariotomy.	Yes.	Died; 10 days; exhaustion.	Eighty-pound tumor; suppurating; hectic fever; pulse 140; very feeble; pus discharging from last tapping.
24. Private ...	November 6, 1886.	43	M.	..	.	6	Multilocular ovariao tumor.	Ovariotomy.	Yes.	Recovered after septic peritonitis.	Sixty-four pound tumor; adhesion to all organs; hot water used to prevent shock; septic peritonitis treated by moving bowels; recovered.
25. Private	November 16, 1886.	42	M.	1			Complication abdominal tumor; sarcoma?	Ovariotomy and removal of large sarcoma.	Yes.	Recovered after septic peritonitis.	Fifteen-pound tumor, ovarian cyst and adherent sarcoma filling whole pelvis; no pedicle; hemorrhage; irrigation of abdominal cavity prevented shock.
26. Private	December 2, 1886.	33	M.	..	.	..	Ovarian tumor.	Ovariotomy and removal of myxomatous mass and fluid from peritoneum.	Yes.	Recovered.	Left ovary size of orange, and filled with jelly-like mass; several gallons of fluid in peritoneum; right ovary had burst, and myxoma had escaped into peritoneum; omentum, and all other organs studded with myxomata; recovered without temperature; drainage kept up for two weeks.

TABLE III.—*Hysterectomies.*

1. Hospital	January, 1883.	63	S.	..	.	.	Epithelioma of the endometrium of fundus uteri.	Hysterectomy, supra-pubic; stump intraperitoneal.	Yes.	Died of shock.	Patient very fleshy and feeble, and confirmed opium habit; died of secondary shock or atropia, given by mistake, in twenty-six hours after operation.
2. Bellevue Hospital.	February 25, 1885.	49	M.	8	1	..	Fibro-cystic myoma tumor, fifty pounds.	Hysterectomy, supra-pubic; elastic ligature externally.	..	Died in 4 hours; shock and hemorrhage.	Tumor fifty pounds; very vascular; small cysts; broad ligament spread out over it; elastic rubber ligature cut and caused severe hemorrhage under the tumor during the operation.

TABLE III.—*Hysterectomies—Continued.*

No. of case.	Date of operation.	Age.	Married or single.	Number of children.	Number of abortions.	Number of tappings.	Diagnosis.	Operation.	Drainage.	Results.	Remarks.
3. Private	April 22, 1885.	27	S.	..	..	..	Fibromata, eight pounds.	Hysterectomy, supra-pubic; wire suture; stump externally.	No.	Recovered rapidly.	Not very vascular; attached to left cornea; only part of uterus and left tube and ovary removed.
4. Private ..	June 8, 1885.	44	M.	1	..	..	Multiple fibromata, fifteen pounds.	Hysterectomy, supra-pubic; wire; stump externally.	..	Recovered.	All of uterus and both tubes and ovaries removed; highest temperature 100°.
5. Private ...	October 10, 1885.	38	M.	..	..	..	Vascular myomata? Very elastic; uterus carried entirely out of reach by vagina.	Hysterectomy, supra-pubic; wire; stump externally.	Yes.	Died in 72 hours from shock.	Large as full term; both tumors under broad ligament and had to be enucleated to secure pedicle.
6. Private	November 26, 1885.	44	M.	1	..	..	Adeno-sarcoma of the endometrium; uterus size of five months' pregnancy.	Hysterectomy, supra-pubic; wire; stump externally.	No.	Recovered.	Patient had been curetted many times, and diagnosis of sarcoma made positive; recovered with very little reaction; highest temperature 100°.
7. Private	September 21, 1886.	44	M.	..	.	..	Multiple myomata; uterus inaccessible from vagina.	Hysterectomy, supra-pubic; wire; stump externally.	No.	Recovered.	Severe hemorrhages, and uterus could not be reached; highest temperature 100°.

TABLE IV.—*Laparotomies.*

1. Private — Removal of kidney.	August, 1883.	..	..	..	.	..	Pyelonephritis; Dislocated kidney.	Laparotomy; removal of kidney.	No.	Recovered.	Intense pain after exercise; kidney filled with abscesses; one of an ounce; pyelitis; complete recovery.
2. Hospital—Ventral hernia and pelvic abscess.	March 18, 1885.	34	M.	3	..	..	Large ventral hernia and pelvic abscess.	Laparotomy; removing abscess and closing hernia.	No.	Recovered.	Drainage-tube had been used; the centre of the abscess was the pedicle ligature of ovariotomy two years before.
3. Hospital—Tubal pregnancy.	June 17, 1885.	29	M.	2	1	..	Tubal pregnancy of left side.	Laparotomy; removal of fœtus, placenta, and tube.	Yes.	Recovered.	Left tube distended by placenta, and fœtus four months' size; suppurating; extensive adhesions; patient had hectic fever.
4. Private—Ventral hernia following laparotomy.	June 24, 1885.	33	M.	1	..	.	Small hernia after laparotomy.	Laparotomy and sewing up hernia.	No.	Recovered.	Hernia, result of laparotomy and drainage-tube.
5. Hospital—Intestinal obstruction.	June 28, 1885.	25	W.	1	..	.	Intestinal obstruction.	Laparotomy and loosening adhesions of sigmoid flexure.	No.	Recovered.	Bands of adhesion, resulting from peritonitis, caused intestinal obstruction.
6. Hospital—Perityphlitis.	August 24, 1885.	22	Male.	..	.	.	Perityphlitis.	Laparotomy.	Yes.	Recovered.	Abscess contained gas and ten ounces of pus; opened and drained; recovery complete in three weeks.
7. Hospital—Exploratory incision.	October 23, 1885.	74	W.	..	..		Abdominal dropsy from cancer of liver.	Laparotomy and drainage.	Yes.	Recovered.	Opened and drained.
8. Hospital—Ventral hernia following laparotomy.	November 19, 1885.	25	M.	..	.		Small hernia after laparotomy.	Laparotomy and sewing up hernia.	No.	Recovered.	Drainage-tube had been used in laparotomy one year previous.
9. Private—Ventral hernia following laparotomy.	November 23, 1885.	37	M.	1	.	..	Large ventral hernia after laparotomy.	Laparotomy and sewing up hernia.	No.	Recovered.	Hernia followed laparotomy and use of drainage-tube.
10. Private	November 27, 1885.	29	M.	3	..	..	Large ventral hernia after laparotomy.	Laparotomy and sewing up hernia.	No.	Recovered.	Hernia followed laparotomy, two years before, and use of drainage-tube.
11. Hospital—Umbilical hernia, irreducible.	January 21, 1886.	47	..	4	5	..	Large irreducible umbilical hernia of several years' standing.	Laparotomy; reducing and sewing up hernia.	No.	Recovered.	Very fat woman; hernia size of cocoanut; skin ulcerating; painful; several years' standing.
12. Private—Ventral hernia following laparotomy.	February 4, 1886.	29	M.	3	..	..	Small ventral hernia after laparotomy.	Laparotomy and sewing up hernia.	No.	Recovered.	Hernia followed laparotomy and use of drainage-tube, six months ago.
13. Hospital	February, 1886.	30	W.	1	..	.	Very large ventral hernia after laparotomy.	Laparotomy and sewing up hernia.	No.	Recovered.	Second operations; about all of the intestines and part of the stomach hang out; the ring and mass reaches half-way to knees.
14. Hospital—General peritonitis.	March 20, 1886.	36	M.	2	..	.	General acute septic peritonitis.	Laparotomy; washed out and drained.	Yes.	Died.	Peritonitis due to bursting pyosalpinx; patient in very bad condition; large gangrenous abscess evacuated; pulse 150, and patient very low.
15. Hospital—Tubercular peritonitis.	April 12, 1886.	32	M.	3	..	..	Abdominal dropsy from tubercular peritonitis.	Laparotomy and drainage; permanent.	Yes.	Recovered.	Opened and drained; general condition much improved by the operation.
16. Hospital—Tubercular peritonitis.	May 26, 1886.	54	M.	5	..	..	Abdominal dropsy from tubercular peritonitis.	Laparotomy and permanent drainage.	Yes.	Recovered.	Opened and drained.
17. Private—Intestinal obstruction.	October 10, 1886.	50	M.	3	1	.	Intestinal obstruction.	Laparotomy; tying and cutting strong band of adhesion.	No.	Recovered.	Peritonitis ten years ago from sounding to diagnose fibroid tumor; complete obstruction for four days; band of adhesion size of lead pencil, completely occluded ileum; recovery complete.
18. Private — Exploratory incision.	December 21, 1886.	35	..	..	..	..	Perforating gall-stone.	Laparotomy; sac not opened.	No.	Recovered.	Fundus of gall-bladder drawn backward, and adherent walls thickened; stone out of reach posteriorly; sac not disturbed.

I have selected two cases that I have recently had to give in detail, so as to practically illustrate what I wished to say about the use of hot water within the peritoneal cavity, during and just after operating, to prevent shock, and the use of enemas and purgatives to prevent intestinal obstruction, and in the treatment of septic peritonitis.

Mrs. C——, from Central New York, aged thirty-eight, married; never pregnant; family history good. Her mother died from the bursting of some kind of abdominal tumor. About four years ago she had a pain in the side and soon noticed swelling of the abdomen. Medicines were given to absorb it, but it grew larger, and more than three years ago it was tapped. Since then she was tapped at intervals four times, and about one hundred pounds of fluid drawn off. Dr. Kay, who had recently taken charge of her case, refused to tap her, and she decided to come to New York.

When I first saw her she was enormously distended by a multilocular ovarian cyst. The ribs were lifted up, and the lungs so compressed that breathing was difficult. Her general health seemed to be fair.

November 6, 1886.—I operated by the median incision. The tappings had caused very firm adhesion to the parietal peritoneum, and it was quite difficult to obtain a point to begin separating the tumor.

After considerable fluid was drawn off, but before general enucleation was attempted, to prevent loss of blood from the adhesions and from the inside of the tumor, which was semisolid and vascular inside, the left hand was passed down to the pedicle, and it was clamped with strong pressure-forceps. This procedure certainly had a marked effect in lessening the loss of blood. Sixty-four pounds of fluid and solid matter were removed.

The tumor was adherent to nearly everything in abdominal cavity; the omentum was tied off, and several points tied in the cavity near the liver and stomach, and deep in the pelvis. After the pedicle was tied and the tumor removed, the oozing was checked by the free use of hot-water irrigation to the whole peritoneum, by means of a large fountain syringe, with a rubber tube of large lumen attached.

I noticed that not only was the bleeding checked by the hot water, but that the indications of shock, which were present to an alarming extent, that is, very feeble heart's action, cold perspiration, etc., were at once relieved by the hot water. Some time was taken to sew up the wound and get her ready for bed, and as there was some return of the symptoms of shock, a gallon of hot water—105° to 110°—was allowed to flow into the closed abdominal cavity by means of the glass drainage-tube that had been inserted, and this was squeezed out and another gallon allowed to flow in and emptied out.

The result was magical. After this the symptoms of shock did not return, and at no time was there a subnormal temperature.

After this she did well until the third day, when the gradual rise of temperature and marked tympanites indicated septic peritonitis.

A turpentine enema was given. Very little flatus and no fecal matter passed; but soon the temperature in the axilla reached 104°, and frequent vomiting of coffee-colored fluid began, and pulse ran up to 140, and there was a slight, irritating cough. Her condition seemed hopeless. Knowing from experience that septic poison is nearly always modified by a free movement, and firmly believing that intestinal obstruction exists in some of these cases from lymph adhesions, necessarily so numerous and extensive, I determined to try and secure a movement by means of a quick purgative.

A full-sized seidlitz powder was given, and supplemented an hour later by an ox-gall enema. A copious brownish-colored liquid movement was the result. After this the vomiting ceased. Nutritive and stimulating enemas were given every three hours, and small quantities of kumyss given by the mouth. The drainage-tube worked well, and large quantities of bloody serum were drawn off three or four times each day. She made a slow but steady recovery, and went home well in seven weeks.

Mrs. H——, of Michigan, forty-two years of age, married; one child eight years of age; no miscarriages. Was always a delicate woman, but had no special sickness until last spring, when she had some pain at menstruation, followed later by dragging pains and a fulness about the pelvis. In July last she was six weeks in bed from a prolonged and very severe attack of general peritonitis. When convalescing she noticed an abdominal tumor, which has lately grown very rapidly, until she is now as large as in the eighth month pregnancy. Examination reveals the pelvis filled with a semisolid, elastic tumor, crowding down in the pelvis almost to the anus. The abdomen is filled with what seems to be an irregular-shaped cystic tumor. Sarcoma was diagnosed, and very little hope given for its removal by an operation.

November 17, 1886.—The patient is a delicate woman, with pulse over 100, and has a slight rise of temperature every night. When the abdomen was opened, a cystic tumor the size of a man's hat was found firmly matted in the omentum and intestines. The adhesions were carefully separated. Several times it was necessary to darn up the torn peritoneal coats of the intestines, a method of stopping bleeding points on the intestines that I greatly prefer to any other. The sutures are passed superficially with a flat, smooth needle, and the bleeding points darned up. The cyst was multilocular, with walls of varied thickness filled with thin, clear fluid. There was no pedicle, the tumor being fed from the adhesions to omentum, intestines, etc. Beneath, and somewhat adherent to the cystic tumor, but in every way distinct, was a vascular solid tumor, completely filling the pelvis. The uterus was adherent to its anterior and upper surface, but was not a part of it. The broad ligaments, with the tubes, were spread out and adherent over the tumor, but were not much enlarged, and were not pedicles. The left ovary was enlarged and cystic, the right was missing, and may have been the cyst above, but this had no direct connection with the broad ligament or tube.

The pelvic tumor was rapidly and boldly separated and removed, every effort was made to remove it intact and completely. It burst, and several ounces of thin, yellowish fluid, resembling pus, escaped. The main attachments of the tumor were in the bottom of the pelvis, and the bleeding was very profuse; the pelvis rapidly filled with blood and obscured the bleeding points. By rapid sponging and the use of several powerful pressure-forceps the principal bleeding points were tied. The whole peritoneal cavity was irrigated with hot water—110°. This not only cleansed the cavity of dirty fluid and blood, and stopped the oozing, but acted in a wonderful manner upon the condition of shock. In this, as in the other case, hot water was forced into the drainage-tube and allowed to run out before placing her in bed. Although her pulse was 140, and very feeble, there was no subnormal temperature and very little sweating. Enough morphine was given to relieve pain and prevent restlessness, and nutritive and stimulating enemas were given every three hours, beginning directly after the operation. Some bloody serum was regularly drawn from the drainage-tube. The second day small quantities of kumyss and pancreatinized milk were given by the mouth. On the third day there was some tympanites, with rise of temperature to 103°. Turpentine enema was given; but spinach green, almost incessant eructations began, and her pulse was 150 to 160. A seidlitz powder was given and supplemented by an enema. A large, dark, watery stool was secured, and the vomiting ceased. By nutritive enemas and careful feeding she gradually recovered, and in four weeks was sitting up. She was about as low as I have ever seen anyone, and yet rally and live.

Up to date there are no signs of a return of the sarcoma.

These two cases fairly illustrate what I wish to bring before the Society.

First.—That hot water cannot only be safely used to wash out the peritoneal cavity, and that it is a simple and efficient hæmostatic for oozing points too numerous and small to tie; but that in prolonged operations, and immediately after the operation, free irrigation of the peritoneal cavity with water at 105° to 110° is a powerful and efficient agent, it lessening, if not preventing, the effects of shock. Towels wrung out in hot water have been used to protect the intestines when turned out of the cavity; but I do not know that hot water irrigation of the peritoneum for shock has ever before been suggested. The temperature of the hot water must not exceed 110°, or it may cause shock.

Second.—That the tympanites and vomiting and other symptoms supposed to be due to septic peritonitis after laparotomy, are best overcome by enemas, and if these fail, by a quick purgative. That in these cases, at least, the bowels should be moved, and not kept constipated, as has been generally practised. That it is probable that in many cases the persistent and exhausting vomiting may be the direct result of intestinal obstruction, the result of bands of adhesions constricting the intestines. For a long time I have seriously doubted the existence of septic peritonitis in some cases where the vomiting preceded the rise of temperature and other symptoms of sepsis. By experience I have found it best to move the bowels whenever indicated by tympanites or vomiting, even during the first twenty-four hours after the operation—of course, making a distinction between these symptoms and those due to the effects of ether. The vomiting from ether is likely to be preceded by marked nausea, and is usually violent and gagging in character, while that from obstruction is passive and more like eructation. The quantity vomited is large, and at first brownish colored, and attended with extreme exhaustion and marked tympanites. Without doubt the opium treatment taught by Dr. Alonzo Clark has proved to be the best plan for limiting local peritonitis, and when carefully carried out may prevent death in some cases of general peritonitis; but I am certain that it is not best suited for septic peritonitis following laparotomy. I usually give enough opium or morphine to relieve pain and restlessness, and keep the respiration down to 16, or even 12 in some cases. But when tympanites or eructive vomiting begins, I at once move the bowels by turpentine or ox-gall enemas, or by a seidlitz powder or Rochelle salts.

I took the hint from a remark of Mr. Lawson Tait, that a brisk purgative would cure septic peritonitis, but the method of effecting it and the explanation as to preventing intestinal obstruction are my own.

Leprosy in Norway.—Dr. Herman Mynter, in 'the *Western Medical Press*, gives an interesting account of a visit to St. Jurgens, the great hospital for lepers in Norway. Regarding the prevalence of this disease he writes: "While in the middle ages the gallows were erected outside the walls of every city to hang every leper who dared to enter, large hospitals are now maintained to take care of these unhappy creatures. A new law has lately entered into force in Norway by which the government has the power to force all lepers into the hospitals, but the opinions about its necessity seem to be divided so far. Leprosy has for years been on the decrease in Norway, from 2,113 cases in 1856 to 1,630 in 1879; possibly on account of the greater civilization and the better knowledge in the population of the disease and of the necessity of its early treatment, possibly on account of the isolation of the infected. The people commence to understand that the earlier the treatment is commenced the better is the prospect of recovery, or, at any rate, such an amelioration of the symptoms that it may be called recovery till a relapse occurs."

THE MEDICATION OF NERVES AND ITS APPLICATION IN THE TREATMENT OF FACIAL NEURALGIA AND OTHER PAINFUL NERVOUS AFFECTIONS.

Being a New Mode of Inducing prolonged Neural Anæsthesia by Pressure applied directly above the Anæsthetic Zone, and consequent Occlusion of the Subjacent Capillaries.[1]

By J. LEONARD CORNING, M.D.,

consultant in nervous diseases to st. francis' hospital, etc., new york.

More than fifteen months since, I succeeded in demonstrating, beyond question, that, in order to prolong the local anæsthetic effects of cocaine, it is necessary to keep the drug in protracted contact with the filaments of the sensory nerves. I have been able to find, in the whole range of medical literature, not a single instance in which this physiological fact of cardinal importance was demonstrated previous to the publication of my first paper. The desultory attempts previously recorded were both scientifically and practically barren of result, and for this reason, that, owing to the slovenly and unscientific manner in which they were conducted, the possible sources of error arising from the effects of local anæmiation of the nerve-filaments or pressure upon the nerve-stems were not eliminated. As a consequence of the lack of knowledge concerning the true physiological *modus operandi* of the drug previous to the publication of my first paper, there was afloat in medical literature much slovenly generalization. Looking back to those days, one can recall to mind all manner of fantastic attempts to explain the peculiar effects of the drug; thus one observer believed that its anæsthetic influence was owing to local anæmia; yet another maintained that it exercised some occult influence upon the chemical constitution of the blood; while some were not wanting who expressed confidently the conviction that the effects observed were the result of hyperæmia. Some there were, it is true, with a large meed of physiological perspicuity, notably Hall, and those who worked with him; but it is none the less true that whatever may have been attempted with bandages or clamps, previous to the publication of my first paper, no true physiological principle had been demonstrated which might lead up to a comprehensive method, which might afford practical aid to surgeon and physician alike. The best proof of this is seen in the fact that methods developed by myself constitute the only comprehensive system of inducing prolonged local anæsthesia to be found in medical literature to-day. And again, this same system is the only one which has promised and achieved matters of magnitude in neurological medicine and surgery alike. These achievements are not the result of the empirical use of bandages, clamps, rings, and the like, but they are rather the result of the application of the law which I was the first to enunciate in all its simplicity, viz., that to prolong the anæsthetic effects of a local anæsthetic it is only necessary to keep the drug in permanent contact with the nerve. All this seems trite to-day, and I should not have referred to it, but for the fact that certain individuals would link my destiny, scientifically speaking, with that of clamps and bandages—appliances which, used at first by myself with a view to the elucidation of sound theory by the rigid application of the laws of induction, had subsequently become merely the instruments for carrying out certain phases of the method, which the knowledge thus gained made possible.

How little the carrying out of the law already referred to is dependent upon the use of clamps or Esmarch bandages I now propose to show; and I shall do this, not with a view to the display of scientific acumen, but rather because I believe that what I have to say will prove of some practical value alike to the scientific physician and his client, who may chance to be a sufferer

[1] Read before the Medical Society of the State of New York, February 1, 1887.

from some painful neural difficulty, defying ordinary methods of treatment.

To begin, then, it must now be clear to those who have bestowed any attention upon the subject, that the longer we are able to expose a nerve or its branches to the influence of a medicinal substance, the greater are the chances of setting up chemical changes of sufficient profundity to insure permanent cure. Prolonged local anæsthesia, or some other form of protracted local medication, is therefore in order in the treatment of a large number of painful neural affections. One of the most common and atrocious forms of nerve-pain is facial neuralgia, particularly when it occurs in advanced life; and yet, heretofore, these same face-pains have been among the most obstinate difficulties to cure in the whole range of neurological medicine. I long since saw in these pains a field well adapted to the use of prolonged local anæsthesia; but I also soon ascertained that the means at hand for keeping the anæsthetic in contact with the nerve-filaments—bandages, rings, clamps, and the like—were not applicable to any extent about the face. I was therefore reduced to the necessity of developing some new method of application, in order to meet these unwonted exigencies. Without premising further, I will give an account of this method; here it is:

1. I first introduce the anæsthetic (cocaine) into the skin by means of the electro-chemical method described by me[1] some time since, or by means of the hypodermatic syringe.

2. When the area in question has been well saturated with the medicament, I cover it with a piece of fine wire gauze.

3. By means of a T-shaped block of wood and an appropriate elastic strap (Fig. 1), uniform pressure is main-

Fig. 1.

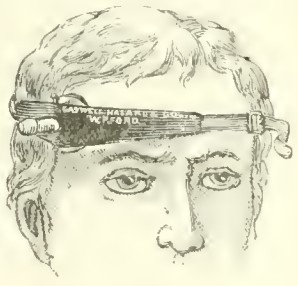

Fig. 2.

tained upon the wire gauze. Fig. 2 shows this simple apparatus in position, when applied to abolish pain in the region of the temple.

With this appliance I have succeeded in inducing cutaneous anæsthesia of one hour's duration on the forearm, and of nearly two hours' duration on the forehead.

The physiological principles involved in this mode of treatment are easily apprehended. When we press upon the tissue above the anæsthetic zone, we simply cause occlusion of the subjacent capillaries. The object of the wire gauze is to distribute the pressure at given intervals throughout the anæsthetic zone. By this means we avoid pressing out the anæsthetic from the tissues, which transpires if we press directly upon the skin with a perfectly smooth surface. Now, by interposing the fine wire gauze, we occlude the subjacent capillaries without pressing out the anæsthetic. This mode of inducing protracted local anæsthesia is far more effective than that involving the use of clamps, rings, and the like. It is also much more universally applicable than are those devices or the commonly employed bandages. For the purposes of neural medication it possesses all the requisites of an ideal technique, being at once universally applicable and wonderfully simple. In surgery it can render little assistance, its chief field of usefulness being, of course, confined to neurology. In this latter field of practice, however, it has unquestionably a brilliant future. I have employed this mode of treatment in various forms of neuralgia, particularly in those varieties occurring about the face. In two cases of occipital neuralgia a cure was effected—in one instance, after one application; in the other, after two applications. It is in those most distressing neuralgias of the supra- and infra-orbital nerves, however, that it has yielded the most brilliant results. In two such cases, which had failed to yield to all other kinds of treatment, I have been able to effect cures. These favorable results I attribute in great measure to the prolonged exposure of the nerve-filaments to the analgesic influence of the medicament.

Where the pain extends throughout the lower portion of the face, and particularly over the cheeks of thin persons, it is difficult to press the wire gauze against the integument with sufficient precision to cause an occlusion of the subjacent capillaries. Under these circumstances I am in the habit of tamponing the space between the teeth and the inner surface of the cheek. This I accomplish by the aid of ordinary cotton-batting. The technique itself is simple enough. The space between the alveolar process of the upper jaw and the cheek is first to be carefully filled out with small pieces of cotton-batting, and the like process is then to be repeated for the lower jaw. The patient is then told to close his jaws, and the anæsthetic may now be introduced and the wire gauze adjusted over the medicated territory and pressed thereupon with perfect facility. The coaptation of the various mechanical features involved is, under these circumstances, all that could be desired.

I have been thus explicit in describing this otherwise simple technique, because experience has taught me that where there is not some inherent mechanical aptitude mistakes may be committed in affairs even the most simple. I know, too, that it is quite as arduous a task, and often, indeed, a far more difficult one, to show just how a remedial agent should be employed under different conditions, than even to discover it.

Finally, I would observe in this connection that where it is a question of medicating deep-seated nerve-stems, as in sciatica, the nerve should be flooded with the anæsthetic before applying the bandage above the seat of injection. I have recently referred at length to this point in an article published in the New York *Medical Monthly*. And when I speak of flooding the nerve, I do not mean the injection of 30 or 40 minims of fluid into the contiguous tissue, but at least from 100 to 200 minims of a one-half to two per cent. solution (of cocaine), according to the susceptibility of the individual to the physiological effects of the drug, and according to the profundity of the chemical impression which it is desired to produce upon the diseased nervous filaments.

I will merely add that I have sometimes re-enforced the influence of the cocaine upon the nerve-filaments by the supplementary introduction of a certain amount of chloroform or ether into the anæsthetic zone. Under ordinary circumstances such a procedure would be intensely painful, but as thus employed there is no inconvenience to the patient.

These, then, are the principal points involved in this plan of treatment, a mode of procedure which, while constituting a radical departure in principle, is eminently simple and effective. In presenting them thus explicitly to this Society, I am guided by the unpleasant realization that, while neuro-pathology has made, altogether, excellent progress, neuro-therapeutics have remained in the background. This state of things is certainly to be regretted by every practical physician; for if it be the duty of the practitioner to make a brilliant diagnosis, it is equally incumbent upon him to cure his client. It is in this spirit, then, that I have presumed to present these considerations to the representatives of the medical profession of the State here assembled.

ICHTHYOL.

By GEORGE T. ELLIOT, M.D.,

ASSISTANT VISITING PHYSICIAN NEW YORK SKIN AND CANCER HOSPITAL; ATTENDING DERMATOLOGIST DEMILT DISPENSARY, ETC.

THE first public mention of ichthyol was made by Schrötter,[1] a chemist of Hamburg, who described, in an article published in 1882, its origin, manufacture, and peculiarities. He had suggested its use in dermatology to Unna, who received it favorably, and reported, a few months later, the results which he had obtained, stating that it did not act injuriously on the skin. Unna[2] described the preparation as being tar-like in appearance, but yet having nothing in common with any of the tars, either in its odor or in its physical properties, and as containing a considerable proportion of sulphur, equal in amount to about ten per cent. ungt. sulphuris. In using it he had commenced with a five per cent. application, but had gradually increased the strength to fifteen and twenty per cent., and though he spoke conservatively in regard to it, yet he seemed to think well of the results obtained in about thirty cases of eczema and some few of psoriasis.

In 1883 Baumann and Schotten[3] entered fully into the chemical nature of ichthyol. In regard to its manufacture, they quote Schrötter (*loc. cit.*), and describe it as being the result of the action of concentrated acidum sulphuricum upon a clear, yellowish-brown oil, obtained by distilling a bituminous mineral found in the Tyrol, which, according to v. Fritsch, contains the fossilized remains of prehistoric fishes and marine animals. The product obtained was neutralized with soda, and going through further manipulation resulted in the preparation already mentioned. From its being, however, a natrium compound, it had to be distinguished from the original ichthyol, and for that purpose, Unna in an addendum to Baumann and Schotten's article (*loc. cit.*) proposed for it the name of "Ichthyolsulfonsaures Natrium," or, as it is now termed, "Natrium Sulfoichthyolicum." A short time after, another compound, the ammonium, was made, and this latter and the natrium one are the two forms in which it is used in dermatology. Since the publication of Unna's first article, the ichthyol preparations have gained a gradual and more extensive use. This is especially the case in Germany, where they have been prescribed not only for diseases of the skin, but also in rheumatism, neuralgia, etc., and if we form our opinions in regard to them from the literature so far existent, we must believe that the results to be obtained are simply marvellous.

The majority of the articles on ichthyol emanates from Unna, who praises it in ever higher and higher terms, so that we are almost led to regard it as a panacea for all dermatoses; yet in this he is followed by quite a number of others. Among these are Küssner,[4] in Halle; Edlefern,[5] in Kiel; Lorenz,[6] Ackermann-Weimar,[7] who separately have used it in all forms of eczema, acne, erysipelas, ambustio, etc., both externally and internally, and also to a small extent hypodermatically. Their opinions in regard to it are all equally good, and they seem to be unable to sufficiently extol its value. In 1885 Unna[8] claimed to have cured a case of leprosy by means of it; while Schweninger,[9] after praising its properties, extends its use to a large number of diseases ranging from lumbago to the acute exanthemata. Cascarina[10] also, in Italy, reports good results; yet it is striking to a dermatologist not to find, until after this latter's article, any recognized specialist in his department, with the exception of Unna, contributing something to the literature of ichthyol. In 1886 Shoemaker, however, gives his experience, and Unna again publishes a voluminous article[1] on the subject, and gives at length the results obtained from its use. Unna had, previous to this, abandoned the natrium combination in favor of the ammonium sulphoichthyol, having found this latter to be much the better.

In this last publication Unna places the ichthyol compounds in a class of reducing agents, which contains pyragallol, chrysarobin, etc., and whose chief action is deprivation of oxygen. It is through this action that it causes hornification of the epithelium of the rete, when locally applied to the skin. When used in weak doses this inherent quality is exemplified in the deeper portions of the cutis by a diminution in the size, by a shortening and a narrowing of the arteries, veins, and capillaries. According to Unna these phenomena, taking place in the blood-vessels, are due to a process which is strictly analogous to the hornification occurring upon the external surface, the diminution in the size of the vessels being persistent, and not the result of a temporary muscular contraction. The cause of this he places in the endothelia, which, accustomed to an overabundant supply of oxygen from the blood, become dry and shrunken, when it is diminished, in the same way as do the cells of the stratum spinosum. On the other hand, when applied in strong percentages its action is the contrary, inflammation being the result. These effects likewise follow the internal use of the drug.

This view of the action of ichthyol upon the blood-vessels is one which is, however, rather questionable. It is a well-recognized and acknowledged fact that the arteries and veins owe their power of contracting to the action of the unstriped muscular fibres in their middle coats, and not to their endothelial lining, so that it is perfectly inconceivable how a shrinkage of the endothelium could produce either a temporary or a permanent narrowing of the lumina of these vessels, since, to do this, it would have to possess the power of shrinking, and of remaining shrunken to such an extent as to entirely overcome and to resist the action of the muscular coats. As far as the capillaries are concerned, they have no muscularis, but are formed only of endothelial cells, and do vary in calibre through the contractile movements of the protoplasm of these cells (Landois).[2] But is it probable that under the influence of ichthyol these protoplasmic movements can be entirely stopped, and that the lumina of the capillary can remain unchanged, regardless of the continually varying movements in the circulation of the blood? If there were a satisfactory explanation of the causation of this it might be more acceptable; but such a one is not given. For it is claimed that, when locally applied, ichthyol produces endothelial shrinkage by diminishing the overabundant supply of oxygen obtained from the blood. Yet the endothelium can get its oxygen from the blood alone, so that a diminution of oxygen can only result from a smaller or a vitiated blood-supply, conditions which demand either narrower vessels, or vessels filled with impure blood. Consequently, to diminish the oxygen, vascular contraction must either occur primarily, or there must be some cause which prevents proper oxidation of the blood. But it is stated that the vascular contraction was the result of endothelial shrinkage produced by limiting the oxygen supply, that is, was secondary, and no mention is made of any change in the blood itself. Consequently, according to this theory of the action of ichthyol, the endothelial changes cause, and are caused by the deprivation of the overabundant supply of oxygen; in other words, they are both cause and effect—an impossibility. Similar objections can be advanced in regard to its action when administered internally. It is claimed that the ichthyol has a peculiar affinity for those particular portions of the vascular apparatus which are

the seat of congestion, relieving it by means of its reducing action upon the endothelium. It would be pertinent, however, to ask how, in congestion, in which there is always poor oxygen supply, the ichthyol can possibly exert any influence, since it acts only on the endothelium, which is overabundantly supplied; and under these conditions how can a still greater diminution of a poor supply of oxygen be followed by a shrinkage of the endothelium? Besides, we are asked to imagine a reducing agent circulating in the blood, and yet exerting no influence upon the red blood-corpuscles, the carriers of the oxygen; and a still more important fact, whether the ichthyol undergoes any change in the passing from the stomach and the intestines to the blood, is not considered or mentioned.

It can thus be seen that the theory advanced, explanatory of the action of the ichthyol preparations, is scarcely acceptable. Possibly future investigations will be able to demonstrate the manner in which they act, but it does not seem at present justifiable to accept the conclusions so far given, which, besides, appear to be based to too great an extent upon *à priori* reasoning.

But to return to the practical side of the ichthyol question. Unna found unlimited use for it in all forms of rosacea, both when given internally and when applied locally. The strength of the application had to be varied according as the affection was indolent and irritable. It also rendered invaluable service in all the manifestations of acne, being superior to everything else when given internally, since, according to his view of its action upon the blood-vessels, it remedies all congestive disturbances of the inner organs.

He found it also especially useful in the treatment of eczemas of a neurotic type, but not to such a great extent in the parasitic forms of the disease. He states, however, that its continuous use in these cases is not advisable, but it should only be applied when new patches appear, other treatment being substituted for the ichthyol when these have dried up. It would, however, seem very doubtful, according to this, to which to ascribe the cure of the eruption—to the ichthyol or to the other treatment. Only the best results were obtained in intertrigo and furuncles, especially of the head, when the drug was used in ten to fifty per cent. ointment, or in a mixture with an equal part of a potash soap. The same beneficial action was exerted in lichen urticatus, prurigo, urticaria, erythema multiforme and nodosum, zoster, herpes, and dermatitis herpetiformis. In erysipelas he recommends a twenty to fifty per cent. ointment, in erysipeloid a five per cent. watery solution. Also as an adjuvant in the treatment of lupus, sycosis, and psoriasis. In addition he enumerates keloid, condyloma acuminata, burns, lepra, cicatrices, seborrhœa, and ichthyosis.

The exceeding praise bestowed upon these ichthyol preparations, both by Unna and the other writers mentioned, induced me to prescribe it and to test it in those forms of cutaneous disease specified by them. To that end I have used it extensively during the last ten months in Dr. L. D. Bulkley's service at the New York Skin and Cancer Hospital, in my clinic at Demilt Dispensary, and in private practice. The results obtained were, however, not entirely as favorable as I was led to expect, but yet for certain classes of cases it proved to be of the greatest value. There were, though, objections to it, which, to a certain extent, were of some consequence, such as smell, taste, etc., and even in dispensary practice it required some persuasion to induce a patient to continue for a length of time its internal and external use. Its beneficial effects were also found not to be as extensive as Unna reported, for in some diseases mentioned by him it was tried for many weeks without any benefit, while it rendered others worse. The strength of the application had to be also much diminished, and only rarely was a ten per cent. one borne. In the large majority of cases when that strength was reached or exceeded the patient complained of its causing a considerable amount of pain and burning, and if persisted in, inflammation resulted. Internally it was for the most part well borne, but especially by children. In adults it was frequently entirely rejected by the stomach, while it nauseated others or caused loss of appetite. In only two cases did it seem to relieve portal congestion, and it had no effect whatever on ordinary congestive dysmenorrhœa. In these cases other remedies had to be used to obtain amelioration of the symptoms present. The dose given internally usually began with three drops, and was increased to eight or ten. It was administered in pill form, in gelatine capsules, and in combination with various syrups. Externally it was used in the form of ointment, in aqueous and in alcoholic solution. Both the ammonium and the natrium sulphoichthyol were prescribed, but the best results were obtained from the natrium combination.

Among the diseases which it was expected would be especially benefited by the ichthyol preparations were those depending upon disturbances seated in the sebaceous glands. They were consequently prescribed in many cases of acne simplex and acne indurata. In acne simplex of the face, either acute or subacute in character, the natrium compound was of no benefit. It was given internally in pill form and in capsules, beginning with four drops and increasing to six or eight drop, and externally as a three to five per cent. and ten per cent. solution, with aqua rosæ or with alcohol. Its use was kept up for one, two, and three months, but during that time there had not only been no change nor improvement in the general character of the eruption and in the patient's condition, but in some cases there was a decided increase in all the symptoms present at the first visit. Yet, when the ichthyol was discarded and other treatment was substituted, the cutaneous affection and general condition progressed satisfactorily in every way. The ammonium combination was also used in some cases of acne simplex which had existed for many years, and which were associated with seborrhœa oleosa of a severe type, the skin of the face being thickly studded with comedones, small papules, and pustules, the patients suffering from constipation and dysmenorrhœa. Persistent use, in increasing doses and strong percentages, produced, however, no amelioration of the conditions present, which remained unchanged until other means for their removal were employed.

In acne indurata the natrium ichthyol was also useless, but the ammonium preparation rendered good service. When applied in five to eight per cent. aqueous solution on the skin of the face and neck, which was the seat of large, deeply situated, indolent lesions, showing no signs of activity but requiring a week or more to run their course, it seemed to arrest their development, to remove the inflammatory symptoms, and beyond a dark red stain marking their former site, to cause their disappearance. This the ichthyol produced quite rapidly, but its continuous use did not, however, prevent the reappearance of new lesions, nor did it in any case bring about a cure, notwithstanding that its internal administration was also kept up for a length of time. It likewise proved to be very serviceable in those cases of acne of the chin seen especially in women, and which are usually so obstinate to treatment. In this class of cases it frequently removed the lesions entirely and effectually.

The effect which the ichthyol preparations exhibited upon inflammation, which was more particularly noticeable in the cases of acne indurata mentioned above, is explained by Dr. Unna as being the result of the narrowing of the blood-vessels. That does not, however, seem to me to be a satisfactory explanation, since it makes the inflammatory conditions entirely dependent upon the blood supply, and leaves altogether out of sight the cause of the inflammation, to which the increased vascular activity is always secondary. An inflammatory process does not originate by increased blood supply alone, but there must be some primary factor which gives the impulse and brings about the vascular changes, and it

would seem more rational to ascribe the cessation of the inflammation to the action of ichthyol upon this primary cause than to the narrowing of the vessels. The inadequacy of the theory is furthermore well exemplified in erysipelas. Its cure under the use of ichthyol is also described as resulting from the vascular shrinkage, while no mention is made, and no account seems to be taken, of the possible effect which ichthyol might have exerted upon Fehleisen's coccus present in the lymphatic and connective-tissue spaces of the corium. It must be granted that ichthyol does effect favorably some inflammatory processes, but I have not found that it did, so far, all, a fact which would also militate against the diminished blood-supply being the absolute and only cause of the subsidence of the symptoms, and for this reason, and also basing my views upon what is known at the present day of the causes of inflammation it does not seem possible to accept the theory in question.

It was stated that in rosacea the ichthyol preparations could be applied most liberally and with the best results, but yet I have to record a failure from their use by me. Both the natrium and the ammonium combinations were prescribed, following the comparative essay which was made for all the diseases in which its effect was tried. They were given internally and applied externally, in doses of from gtt. v. to x., and in aqueous solution, and in form of ointment from three to ten per cent. The treatment was kept up in some cases for three months, and yet absolutely no change was observed in the dilated condition of the capillaries, which were just as prominent and evident as before. When acne pustules were present, constituting acne rosacea, they were, however, removed by the ichthyol and the skin became smooth, but the redness remained. Yet, when we compared these results with those obtained from the treatment generally followed, the use of ichthyol offered not the least advantage, for without it the acne lesions could be removed as rapidly as with it, while the dilated vessels could be destroyed, and the redness be caused to disappear in much less time than was taken for the experimental use of the ichthyol preparations.

In regard to eczema, the most varied results were obtained, and its efficacy was in a large number of the forms of this affection questionable. Unna (loc. cit.) makes two divisions of eczema—the parasitic and the neurotic—a classification which I cannot say is borne out by my experience in the many hundred cases of this disease treated yearly by me. Yet, for the sake of testing the benefit to be derived from ichthyol, I followed as closely as possible the description given of the neurotic cases. Several, in which the eruptions occurred in rather circumscribed patches studded with papules, vesicles, etc., situated around both wrists, ankles, and knees, characterized by acute recurrent outbreaks after the process had seemed to have disappeared entirely, were given the ammonium ichthyol internally, and were treated with it locally. Though its use was kept up in one case for four months, in another for three months, and in a few others for varying lengths of time from one to two months, no benefit was derived. The new patches dried up rapidly from its use, it is true, but recurred again without seeming to care in the least about the internal effect of the ichthyol, and not until other treatment was substituted for it could the process be brought to a standstill.

In that class of cases termed parasitic its use was also a limited one. It benefited some temporarily, while others were entirely uninfluenced by it. In acute pustular or vesicular eczema it was not tried, nor in the chronic squamous form of the disease. But in chronic eczema rubrum and in acute outbreaks upon chronically thickened areas of skin, especially when situated upon the legs, depending upon a varicose condition of the veins and associated with those ulcerations known as varicose, ichthyol gave at times marvellous results. The natrium preparation produced here also the best effects, while the ammonium ichthyol caused, even in very weak percentages, pain, burning, and an increase in the inflammatory symptoms. Its advantages were seen more especially in its keratoplastic action, which was very marked in those cases, which, having been brought to a certain point in healing, yet resisted for weeks every attempt made to bring about the formation of solid horny epidermis over the weeping surfaces. In these cases a three to five per cent. aqueous solution of the natrium ichthyol gave immediate benefit, and often after two or three days' use these patches of eczema rubrum were found entirely dry and covered over with epidermis. The same beneficial effect was exerted by the ichthyol upon small superficial ulcerations associated with this condition of eczema rubrum, and one feature was noticed which spoke strongly for the keratoplastic action of the drug, viz., the granulations filling up the base of the ulcer were rapidly covered with horny epidermis, so that there very often resulted a depressed cicatrix, the level of which was that of the height of these granulations previous to the application of the ichthyol.

In the seborrhœa oleosa, situated so frequently around the alæ nasi and upon the cheeks, and accompanied by a considerable amount of congestive redness, the ammonium ichthyol gave very good results, but only when used alternately with other treatment. I had observed in several cases that its use was followed by considerable improvement for the first few days or a week, but after that remained in *statu quo*. If the strength of the application was increased a slight benefit again ensued, but ceased again after a few days, and it occurred to me to stop its use for a short time and then to reapply it. Its good effect was readily manifested by this manner of proceeding, and consequently I continued its use as an alternate application, either every other day with another lotion, or one week ichthyol, one week the other. The explanation of this I would find in the keratoplastic properties of the ichthyol, which, causing a greater and denser formation of epidermis to take place, prevented materially the action of the drug upon the tissues below, so that it was necessary to either increase the strength of the application in order to produce an effect, or to remove by other means the dense horny layer, and thus allow the ichthyol to act upon the fat-glands, etc. I can only add that when it was used in this manner the results obtained were all that could be wished for.

In intertrigo the action of the natrium preparation was remarkably satisfactory, but that of the ammonium was not so good. It was used quite frequently in this affection, which is so common among children, and after a very few days, instead of the bright red, moist surface so characteristic in the inguinal region, and on thighs, buttocks, and abdomen, there was found a dry, slightly reddened skin, or one which was entirely normal. There was no distinction in regard to the age of the patients for whom the ichthyol was prescribed, but the same beneficial effect was obtained in babies a few weeks old and also in adults. In these cases an ointment of the strength of two to ten per cent. was invariably used.

In dermatitis in general, but more especially in those forms which were septic in their origin, and in panaritium, the ichthyol preparations were exceedingly useful both in allaying the pain and in stopping the process.

In burns of the first and second degree the natrium compound gave remarkably quick and good results, removing the pain and soreness and hastening the formation of new epidermis. In several cases in which the skin of the entire hand and arm had been raised up, forming large bullæ, while here and there were patches of variable size on which it had been completely destroyed by boiling lard or steam, the application of an aqueous solution (five per cent.) not only brought about a rapid subsidence of all pain and inflammatory symptoms, but absolute healing resulted in from five to ten days.

In urticaria the advantages claimed were not found.

I only used the ichthyol in chronic cases of this disease, since the acute attacks not only get well of themselves, but their cure is a matter of such ease that their being benefited by ichthyol would prove nothing. It was prescribed, however, for those patients who had been suffering for some time with constant daily recurrent attacks, which could not be traced to either animal parasites, improper food, or any special gastric or intestinal disturbance. Its use was both external and internal, but though in some cases immediate relief was obtained, yet the urticaria returned again in a few days after its administration was stopped, notwithstanding that it had been taken by some patients for one, two, and three months. In other cases no effect whatever was obtained.

The ichthyol treatment was not found to give better results in ichthyosis than other preparations, and while in pruritus its effect was at times very good, yet at others it was absolutely nil.

As an adjuvant in the treatment of lupus, the natrium compound acted remarkably well. After the use of argentum nitricum, or the sharp spoon, the application of a five per cent. ointment—a stronger one was not borne—not only gave the patient great relief, but also brought about a speedy cicatrization of the surface.

The effect of the ammonium compound on cicatrices was also very satisfactory. It softened the dense and hypertrophied ones, caused a great diminution in their size, and allowed a return of a certain amount of natural pliability to the skin. As a rule, a five per cent. ointment was used, and though a portion of the good result was undoubtedly due to the rubbing, yet the advantage of the ichthyol was seen in the more speedy improvement than when massage alone was used. Naturally in an exclusive dermatological practice there is very little opportunity for treating rheumatism or neuralgia, or any of the other general maladies for which ichthyol has been greatly extolled, and though it was used in a few cases in which these affections were coexistent with the skin disease, and gave immediate and most marked relief of the pain, yet owing to the limited test made, I would not venture to draw any conclusions, either *pro* or *con*.

The trial and testing of the ichthyol preparations, the results of which have just been detailed, were not limited to a few cases, but they were prescribed for a large number, in order that warrantable conclusions might be drawn, and I have omitted mentioning affections such as keratosis palmaris et plantaris, psoriasis, erythemata of neurotic origin, etc., in which it was used only once or twice, and in which the results were variable, since I did not consider the number of cases allowed a decision to be made. When, however, a general review of the results obtained from ichthyol in my hands is made, it must be evident that they are far less favorable than those published in the foreign literature, and instead of its applicability to cutaneous disease being almost universal, there would seem to be, on the contrary, rather a limited use for it, and one which, outside of certain special forms of eruptions and functional disturbances in and on the skin, offers not only no advantages over, but is much inferior to, other and older methods of treatment. For those special classes of cases I must unquestionably praise its efficacy, but further than that my results do not allow me to go.

The latest religious sect in Russia has been founded on the dogma that it is a sin to let a fellow-member suffer the martyrdom of disease. Accordingly, when anybody falls sick, one of the believers goes to him and chokes him to death. The person commissioned for the deed is clad in red clothes, and is known as "the red death." Unfortunately, they do not confine their delicate attentions to the members of the sect alone, but, impelled by a broad charity, seek to cure in their peculiar way anyone, whoever he may be, who has the misfortune to become ill.

Clinical Department.

INTUBATION OF THE LARYNX—RECOVERY.

Dr. A. Caillé, Attending Physician for Diseases of Children at the German Dispensary, New York, writes: "On the evening of February 3, 1887, I was requested, by Dr. C. F. Kremer, of this city, to intubate in a case of diphtheria with progressive laryngeal stenosis. The patient, a girl five years of age, came under observation January 25th, after having suffered for several days. The first croupous symptoms set in January 27th; corrosive sublimate, in small doses, was administered internally, and inhalations of a mixture of boracic and salicylic acid solutions ordered. Moderate dyspnœa and cyanosis persisted for a week, during which time shreds of membrane were expectorated daily. On February 2d there was an increase in the dyspnœa and cyanosis. The patient was found in her mother's lap, with cold, clammy skin, cyanotic countenance, and hardly able to struggle for want of strength. Respiration was extremely laborious and slow, with deep recession of the chest-wall at each inspiration; pulse weak, exceeding one hundred and fifty beats per minute, and intermitting at each respiratory atttempt.

"Râles present all over thorax, and no appreciable respiratory murmur. Inspection of the pharynx showed two small diphtheritic patches on the posterior pharyngeal wall. After introduction of a proper-sized tube, which was accomplished without difficulty, a large quantity of watery mucus streaked with blood was expectorated, whereupon the child ceased coughing and breathed with great ease. On removal of the gag and string the patient asked for water in a hoarse whisper, but every attempt to swallow provoked an attack of coughing.

"Twenty minutes after the introduction of the tube the child showed a good color, satisfied expression, was placed in bed and soon went to sleep. In order to avoid a possible pulmonary complication, rectal alimentation was decided upon. An enema was given every three hours. Not a particle of nourishment was swallowed as long as the tube remained *in situ*, *i.e.*, four days.

"On the morning following the operation the temperature was normal, pulse slow and somewhat feeble, with good pulmonary resonance, vesicular breathing, and moist râles all over the lungs.

"On attempting the removal of the tube, in the afternoon of the fourth day, it was found firmly fixed in the larynx by a fold of mucous membrane from the laryngeal surface of the epiglottis, probably œdematous, which had to be pushed aside by the finger before removal of the tube was possible.

"For about an hour after this every attempt to swallow provoked an attack of coughing. On the following morning I made a laryngoscopic examination, which revealed a hyperæmic condition of the epiglottis and vocal cords, but no decubitus. I was not able to obtain a good view of the trachea. A diphtheritic patch was still present on the posterior pharyngeal wall, which remained visible for several days. The child made an excellent recovery and is perfectly well at the present time.

"I am permitted to state, in behalf of Dr. Krémer, who has had an extended experience in the treatment of similar cases, that 'the complete relief afforded by the intubation in this case, and the absence of the necessity of any after-treatment, impressed him very favorably with the O'Dwyer method.'

"Comparing the utility of this method with tracheotomy, it is the opinion of the writer, based upon an experience in twenty-one cases with five recoveries, in all of which the latter operation was resorted to, that intubation is preferable to tracheotomy in many cases of laryngeal stenosis.

"In conclusion, the following suggestions are sub-

mitted: 1. Intubation should, as a rule, not be resorted to before actual cyanosis has set in. In the treatment of 'croup' good judgment as to the proper time for active interference is essential. 2. The thread attached to the tube should be as long as possible so that it may be grasped before it gets out of sight, in the event of its having been slipped into the œsophagus. 3. The calibre of the tube could be enlarged, and the advantage of weight retained, by adopting a metal of high specific gravity—viz., platinum, specific gravity 21.5—for its construction, thus facilitating expectoration of false membrane. 4. The danger of pulmonary complication arising from the possibilty of the entrance of foreign substances into the larynx should be avoided by resorting to rectal alimentation or feeding per stomach-tube, after intubation. 5. Dr. Denhard's modification of the gag is worthy of recognition, as it enables the person holding the child's head to control the gag, and avoids displacement of the latter."

PECULIAR EFFECT OF COCAINE.

Dr. J. W. Stickler, of Orange, N. J., reports the following: "On January 21, 1887, a patient came to me, presenting a small cyst in connection with the extensor tendon of the middle finger of the left hand.

"After introducing into the cyst about five drops of a twenty per cent. solution of cocaine, I opened the sac and evacuated its semi-fluid contents. In less than half an hour the finger began to swell, and in less than two hours the swelling was extreme. Very soon systemic disturbance became manifest in the following symptoms: dizziness, headache, pallor of skin, nausea, and diarrhœa. During the first night the patient slept but little.

"January 23d.—Finger swollen, tender to touch, somewhat painful, red and hot, but not œdematous. Same constitutional condition as previous day.

"January 24th.—Finger has same appearance as on the 23d; no œdema; the hand somewhat swollen and slightly œdematous. Diarrhœa has ceased. Nausea slight when patient sits up or walks. Still complains of dizziness.

"January 25th.—No change in the appearance of the finger, but the hand is more swollen. No evidence of suppuration. Patient able to sit up without suffering from either nausea or dizziness.

"January 26th.—The swelling of the finger is somewhat diminished, although it is still tender, and somewhat painful. The general disturbance has disappeared, but the appetite is greatly impaired. After the last date the swelling subsided quite rapidly, so that by the last of the month the use of the joint was regained.

"As has been said by others who have written concerning the effect of cocaine, congestion is of frequent occurrence, but I have witnessed only this one instance of alarming congestion following the hypodermatic use of the drug. I call the condition 'congestion,' because the enlargement of the finger reached its utmost limit in about two hours after the use of the cocaine, and the finger had about the same appearance as would have been produced by constriction of the part with an elastic band.

"The systemic disturbance was also more pronounced than is usual. I am, therefore, led to believe that the hypodermatic use of strong solutions of cocaine is attended with considerable risk, unless it is known prior to its employment just how susceptible the patient may be to its influence."

MANAGEMENT OF TEDIOUS LABOR FROM RELAXED ABDOMINAL WALLS.

Dr. H. L. Ellis, of Brooklyn, writes: "In those very common and vexatious cases of labor in multiparæ, where the abdominal walls are lax, the pains nagging, and progress *nil*, and yet where no obstruction or malpresentation exists, I employ an expedient so simple, safe, and effective, that, at the risk of learning that my device is old, I will describe it. To me it is new; nor have I seen it mentioned. If one will watch the abdomen in these cases he will notice that it is giving not only no assistance, but no support to the uterus, and that, as a result, there is practically no *vis a tergo*, the force of the uterine contractions being almost equally dissipated in every direction. To furnish the necessary resistance, I girdle the patient's abdomen with a strip of elastic webbing, eighteen inches wide by four feet long, having several transverse rows of eyelets in one end, and a row of hooks in the other. This I apply snugly in an interval between the pains. The *next* pain almost invariably leaves the girdle from one to two inches slack. I then advance the hooks till all is again snug, and so on; my experience being that from four to six pains accomplish delivery. It is noticeable that these are *good* pains, often the first the patient has had, and are, I believe, the direct result of the support and resistance supplied by the girdle. I believe, too, that when this manœuvre is resorted to, the uterus does not become so exhausted, and hence is not so liable to subsequent relaxation and hemorrhage. A good substitute for the elastic webbing is a stout towel, fastened with four safety-pins. It is easily applied, supplies a firm, evenly distributed pressure, is readily regulated, and, I believe, will safely and speedily end many an anxious vigil."

AN OBJECTIVE PERCEPTION OF CORRIGAN'S PULSE.

Dr. E. Meierhof, Attending Physician, Out-door Department, Mount Sinai Dispensary, communicates the following: "Generally speaking the pulse is a subjective phenomena, but recently I had an opportunity to observe the pulse by the eye. A patient having marked cardiac disturbance involving both mitral and aortic valves came under observation. An examination of the radial and carotid arteries revealed the condition frequently observed in aortic disturbance, the so-called water-hammer pulse of Corrigan. Continuing my examination it occurred to me to use the ophthalmoscope to see if any disturbance of the branches of the arteria centralis retinæ could be observed, although the patient did not complain of any disturbance of the visual organs, nor did there appear any. In the erect image it was observed that with the synchronous movements of the carotid artery the main branches of the retinal artery made marked excursions in contracting and dilating, the movements resembling those made by whip-cord when cracked; the undulations naturally being from the trunk of the artery outward to its branches. The examination was made three times at intervals of five days. The patient when first seen was ordered digitalis, etc. At the third visit, which was at the end of two weeks, the undulatory movements referred to were unobservable, but while the radial pulse did not show the same amount of disturbance as was first observed, the carotids were still noticeably disturbed, the difference no doubt being due to the difference in the size and situation of the vessels. What benefit such an observation can have in dealing with disorders of the circulation I am at present unprepared to answer, but it demonstrates the growing utility of the ophthalmoscope in general practice for observing not only disturbances of the cerebro-spinal nervous system, but also those of the circulation. It is possible that some means may be discovered or invented to determine the condition of the blood through the medium of the vessels of the fundus oculi, the walls of which are transparent. One of the first observations made of the fundus oculi in connection with the circulation was due to embolism of the arteriæ centralis retinæ. A case under recent observation revealed the coincidence of endocarditis and muscular rheumatism, thus showing also that the circulation plays a direct and important factor in disturbances of the eye."

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, March 19, 1887.

THE EARLY DIAGNOSIS AND REMOVAL OF TUMORS OF THE BLADDER.

VESICAL neoplasms are generally admitted to constitute a variety of tumors of difficult diagnosis, at least in their incipience, of great gravity to the patient, and frequently of considerable perplexity to the surgeon. Dr. Guyon, in a recent communication to the *Progrès Medicale*, shows that an early diagnosis is sometimes possible, and should be followed by immediate removal of the offending growth. Although we are disposed to doubt the propriety of calling excision a "radical cure" in cases of malignant new-formations, we gladly admit that early interference is based on sound surgical principles and constitutes far better practice than the fatal policy of procrastination.

According to Guyon, hæmaturia, when persistent and uninfluenced by the external conditions of the patient, such as bed-rest, hygienic surroundings, and appropriate treatment, justifies the diagnosis of a neoplasm seated somewhere in the urinary passages. In the particular case forming the basis of his remarks, Guyon also emphasizes the absence of frequent micturition. An important aid toward localizing a new-formation the French surgeon finds in the presence or absence of symptoms allied to renal colic. Whenever the kidney becomes the seat of destructive lesions producing hæmaturia, painful symptoms occur; but when tumors invade it, little or no discomfort is felt.

As a further diagnostic point, Guyon asserts that when a kidney increases in volume it becomes movable. This gives rise to a new physical sign, which he has named *ballottement rénal*. In order to ascertain its presence, bimanual exploration is necessary.

Two fingers are placed behind, above the ilium, and by a succession of little shocks the attempt is made to force the kidney against the other hand placed lightly over the antero-lateral abdominal region, which corresponds to the location of the organ to be examined.

In order to accurately localize a vesical neoplasm, conjoined manipulation is always essential. The bladder is completely emptied, and, with one finger in the rectum, the surgeon's other hand forcibly presses down the supra-pubic region. For the internal exploration of the bladder Guyon employs only soft instruments, which are without danger to the patient. Finally, to convince himself that the blood comes from the bladder, he recommends the following simple procedure: First, empty the bladder, then wash it several times until the injected fluid returns clear, and now direct the patient to empty the bladder himself, at the same time assisting the manœuvre by gentle pressure. If bright-red, sanguinolent fluid appears, the source of the blood is sure to be in the bladder.

In Guyon's case the microscopical examination of the urine was entirely negative, and he thinks this is generally so in recent tumors. We cannot accept this statement, believing that the character of the growth, and especially its consistency, will influence the point in question. In the very soft and friable neoplasms histological elements appear early in the urine, whereas in the opposite forms they may be missed, even at a late stage of the disease. The age of the growth is of only secondary moment in this connection.

From this brief description of the essential points in Guyon's method of early diagnosis, it will be seen that it is applicable to many cases, but also that it will not succeed in all. All the symptoms mentioned by him may, indeed, be observed in tuberculosis of the bladder, and some of them may be absent in cases of very small, hard growths.

As regards the operative procedure of the French surgeon, it consists in simple ablation, followed, when necessary, by excision of the vesical wall. Guyon, in carrying out excision, proceeds from within outward, claiming that this is a better method than that of Sonnenburg and Antal, because it permits the surgeon to perform a "regular and complete dissection" without any danger of separating the bladder from its anatomical connections.[1] But excision is only necessary in those cases where the malignant tumor is already surrounded by a zone of infiltration. Guyon has found, however, that such infiltration occurs earlier than is generally supposed. And it is precisely in this circumstance that he finds the justification for the earliest possible interference consistent with scientific accuracy of diagnosis.

In all those cases where the tumor is not surrounded by infiltration, Guyon simply removes the projecting portions, then scrapes the base, and, after cauterization, closes the vesical wound with catgut sutures cut short and allowed to remain.

THE MORTALITY OF TYPHOID FEVER IN NEW YORK.

WE have received a number of letters from correspondents in different parts of the country, expressing surprise at the high rate of mortaltity from typhoid fever in this city. Some suggest special modes of treatment, the adoption of which they think will be of service in reducing the high death-rate of the disease, while others kindly intimate that if "New York doctors were less scientific and more practical, a diagnosis of typhoid fever would not always be equivalent to a death-sentence."

These letters have been called forth by a paper read before the Section on Practice of the Academy of Medicine, and published in THE MEDICAL RECORD of January 8, 1887. The writer gave the mortality-rate for the

[1] Sonnenburg, of Berlin, and Antal, of Buda-Pesth, performed resection of the bladder by cutting down upon it from above, and thus opening the peritoneal cavity. Sonnenburg stitched the cut ureter to the abdominal wall.

past ten years, based on the statistics of the Board of Health for that time. These statistics showed that there were 7,712 cases reported, of which number 3,184, or 41.28 per cent., died.

These figures, we feel compelled to say, are misleading, and do not indicate, even approximately, the actual mortality of the disease. The statistics of the Board of Health are necessarily accurate, excluding errors of diagnosis, as regards the number of deaths from a given disease, but they are notoriously inexact as far as concerns the number of cases actually occurring. And the same holds true, though not to so great an extent, concerning the birth-rate. The reason why the figures are inexact is not through any fault of the Board of Health, but is simply the fact that physicians do not report their cases. Many physicians who ordinarily report cases of contagious diseases do not consider typhoid fever sufficiently contagious to warrant a report, and many others do not report any cases, unless they anticipate a fatal issue. Indeed, instances are by no means rare of a report of a contagious disease being withheld until just before the death of a patient, when, in order to escape the possible danger of an enforcement of the penalty for non-compliance with the law, the Health Board is notified.

That this is so, a little reflection will convince anyone, for it is very evident that there must have been an average of more than seven hundred and seventy-one cases of typhoid fever per annum in this city during the past decade. And it therefore follows that the mortality of the disease is not so high as these figures would lead one to suppose.

SEXUAL DISORDERS AND SYSTEMATIZED QUACKERY.

The increased number of quacks and quack-agencies in this city appealing to victims of sexual troubles and of venereal disease, and the boldness and offensiveness of their advertising methods, are working an injury which demands more than ordinary notice. In late years the older methods have changed, and, from a business point of view, improved, and it has become the practice for these quacks to work under the guise of agencies or companies. They have "laboratories," consultation-rooms, and most elaborate methods of advertising by circulars, hand-bills, and through the lower grades of newspapers. So complete is the system that there is hardly a young man or growing youth in the city who does not get hold of some disgusting, or, to him, terrifying notice, picturing the horrible results of self-abuse and seminal losses. Thousands are thereby frightened into a mental state half approaching insanity. Many of them go or write to some of these advertising firms, put themselves under treatment until every spare penny has been wrung from them, without, as a rule, any good being done. On the contrary, an increase in their troubles often results, and even a permanent state of mental and nervous depression is brought about.

The young man once in the toils of these unholy "agencies" is subjected to influences tending to keep him there. There seems to be a list kept of those applying at one place which is circulated among quacks all over the country. Consequently the once victimized party is in constant receipt of new circulars describing the virtues of new "pearls," or pills, or special apparatus. Many of the circulars contain grossly inaccurate descriptions and illustrations of the sexual apparatus, the bladder, stomach, brain, etc.

We have before us a specimen circular, depicting with equal force the despairing future of the masturbator and the unequalled virtues of a certain suppository. It has also cheap wood-cuts of "a brainless child born of a masturbator," a hydrocephalic child with the same ancestry, and of a half-naked man behind the bars of a cage, representing a person "made insane by self-abuse!" No words can tell the agony, the shame, the despair, which such publications cause in a large class of half-educated youths who get hold of them.

A young man, subsequently found to have a fine physique, no actual sexual weakness, and to be suffering only from two or three emissions monthly, wrote to a physician: "Although I am able to work, yet every day the constant thought of my condition, my blasted and miserable life, is with me always, and keeps me in a constant despairing state of mind."

This is the "state of mind" which it is the aim of the quacks in question to produce to as large an extent as possible. The more morbidness and despair, the more money in their pockets, for they fatten on the distress of their victims. Here is the foulest possible prostitution of medicine, a systematized attempt to create disease and then get money from it.

These individuals and companies do not confine their practice to sexual troubles, but plaster the telegraph poles and other places with announcements of "swift cures" for "private diseases," and send circulars advertising cures for all kinds of chronic troubles. Blanks are furnished, to be filled out with information regarding the person and the disease; descriptions of how to send urine by mail, price-lists for different sets of pills, or different courses of treatment, are also furnished.

In fine, these establishments have become a public nuisance to the intelligent community, and a serious public harm to those unable to judge of their merits and honesty.

THE DEMONSTRATION OF ISOLATED TUBERCLE-BACILLI.

Biedert has for years been engaged in studying tubercle-bacilli, mainly from a practical and clinical stand-point. He has recently published in the *Berliner klinische Wochenschrift* a method for the detection of these microbes in cases where they occur in such small numbers that the ordinary processes now in vogue may fail to reveal their presence. It is scarcely necessary to point out the importance of detecting even the smallest number of the bacilli in question. Those who are convinced of the correctness of Koch's views regarding the specific nature of tuberculosis will require but a single bacillus to give them the clue to a suspected case. The unbelievers, on the other hand, will fail to be convinced by the demonstration of myriads of microbes. For the believers, then, a single bacillus will speak as plainly as countless numbers could, since it has not yet been clearly shown that their abundance signifies anything more than their presence in very small proportions. In either case we are told to assume a specific tubercular process. But more than this we are not yet at liberty to infer.

Biedert proceeds as follows: He takes about a table-

spoonful of the suspected sputa, and adds thereto twice that quantity of water and fifteen drops of a strong solution of soda.[1] This mixture is boiled until it becomes quite fluid, and then diluted with about two ounces more of water. After being again boiled the mixture is nearly homogeneous, and free from lumps and particles. If on cooling a thin fluid does not result, more water may be added. A conical vessel now receives the mixture, and after two or three days the supernatant fluid, having deposited its bacilli, can be decanted. The sediment, after energetic stirring, can now be examined in the ordinary manner. A practical point deserves notice in this connection. The addition of soda to the expectorated matter renders its albumen soluble, and after drying the film may scale off the glass during immersion in the staining fluid. To obviate this, Biedert advises that a little fresh egg-albumen be added to the drop of sediment which is to be spread on the glass. It may then be safely dried and passed through the flame as usual. It may be here stated that this new method is not available for sections of tissue.

Biedert regards his process as an eminently trustworthy test for bacilli. It certainly does away with the tedious and time-robbing method of examining numerous cover-glass specimens. For practical purposes it may be well to collect the sputum of several days, especially where expectoration is scanty.

Biedert says, in proof of the success of his method, that sputum examined in the ordinary way may show very few bacilli, whereas the same sputum, subjected to the above treatment, will be found to fairly teem with them. The most favorable time for examining the mixture is after two or three days' standing. After that period no further increase in the number of bacilli is found. As a further proof of the utility of his method, Biedert says that if he mixed a tablespoonful of sputum, known to be without bacilli, with a single drop of tubercular sputum, specimens prepared in his way invariably gave positive results.

It is surely not too much to say that the great majority of physicians nowadays attach a certain amount of value to the discovery of tubercle-bacilli in the sputum of patients having chronic lung-trouble. By all these Biedert's method will be received as a welcome addition to practical bacterioscopy.

[1] In a later issue of the Berliner klinische Wochenschrift (No. 2, 1887), Biedert states that seven to eight drops are usually sufficient, since fifteen drops occasionally interfere with the ready staining of the bacilli.

THE WORKING-TIME OF THE PHYSICIAN.

Statistics have at various times been published showing the mortality-rates among physicians and the causes of death. But we have met with no such careful analyses of the life-history of the medical body as have been furnished by Dr. Friedrich Böhm regarding the physicians of Bavaria (*Münchener med. Wochenschr.*, No. 4, 1887).

In the year 1886 there were in Bavaria 1,787 physicians. The average age of these was 45.3 years. In cities of 10,000 inhabitants the age was somewhat higher—viz., 48.7, while in the country it was 44.3. This fact is due probably to older physicians moving to the city after having accumulated sufficient means or earned sufficient reputation to enable them to do so.

The average age of physicians in 1863, twenty-three years before, was 24.7 years; and the decline is due to the relaxation in requirements, which has brought a larger element of young men into the profession.

This is shown in another way. From 1854 to 1886 the percentage of physicians between the ages of twenty-four and forty has steadily risen from 27.4 (in 1854) to 44.1 per cent. (in 1886). The proportionate number of physicians between the ages of forty and sixty—in other words, the working-time of physicians—is not in such narrow limits now as formerly. Among 1,000 doctors there are 441 between the ages of twenty and forty, 394 between forty and sixty, and 165 above the age of sixty.

The youngest age at which medical men are found in Bavaria is twenty-four, and the age of those beginning practice ranges from twenty-four to twenty-six years. Twenty years ago the age was from twenty-five to twenty-eight. This is all in most extraordinary contrast with the state of things in this country, in which the average age of medical college graduates is certainly not over twenty-three years, while many are graduated who have barely passed their majority.

The average duration of life of the physician is not given, but the figures collected show that of 100 physicians starting in practice 63 die before the fiftieth year, 82 before the sixtieth year, and 90 before the seventieth year. Only ten per cent. of those who start out in medical life, therefore, reach the allotted period of threescore years and ten.

This is not a very good showing, but it is an improvement on the state of things thirty years before, when, according to Dr. Böhm, only five per cent. reached the period in question.

SHALL PHYSICIANS PAY FOR THEIR MEDICAL SERVICES.

In the Annual Address before the American Dermatological Association, made last year by the President, Dr. Edward Wigglesworth, some sentiments were expressed which will be likely to arouse discussion and protest. He says:

"The day has gone by for remitting fees to clergymen, or even to other physicians. The necessity for such a condition of things, due to the mutual relations of the single parson and the two physicians of country villages, a century ago, has gone forever. The members composing the medical profession furnish to-day a gratuitous clientèle enough to occupy the whole time of the best specialist, who is naturally the adviser selected, and thus to ruin him financially. If he does not in return ask advice from each of those he has treated, and he cannot, even if he would, of all—then where is the *quid pro quo* upon which the whole absurdity is based? The particular one whom he does select as his family-physician makes, naturally, more visits to the family of the specialist than the latter is likely to return, and should be remunerated accordingly. Business is business, and exactness in money matters promotes good feeling. In Boston, I rejoice to say, the specialist pays his family-physician, and feels for him a warmer regard and a more

cordial appreciation in consequence, while at the same time preserving his own self-respect."

Dr. Wigglesworth appears to think that the physician should not be expected to render a service unless there is a *quid pro quo*. This is placing our profession upon a mercantile basis with a vengeance. It has been taught in days gone by that there was something above trade in the practice of our art; and one of the best evidences that we were more than a guild of tradesmen has been the fact that our professional services were to be freely and gladly extended to all brother-practitioners of medicine. The sentiment which prompts physicians freely to extend mutual help will, we trust, never die out among the mass of the profession, whatever may happen to the specialists.

The view advocated by Dr. Wigglesworth is a plain announcement of the fact that the specialist expects to be paid when a general practitioner goes to see him, and that he, the specialist, expects to pay his family-physician.

A case in which this subject acquired a curious medico-legal importance recently came up in St. Louis. The late Dr. Van Studdiford, an old, wealthy, and retired physician, during his last illness called in Dr. Waldo Briggs. The case was difficult and arduous, calling for attendance at all hours of the day and night. After the patient's death, Dr. Briggs (after consulting with professional friends) presented a bill of $500, which was allowed by the Probate Court. Against this the widow and family appealed, basing their action mainly upon the ground that it was "not customary for one practitioner to charge another." The Court decided in favor of Dr. Briggs.

SURGERY IN TEXAS.

We have received the report of the Special Committee on Surgery, appointed by the State Medical Society of Texas, Dr. George Cupples being chairman and reporter. It makes a quarto of seventy-two pages and embraces the tabulated statistics regarding 4,293 operations performed by Texas surgeons. The report is a valuable one; it represents an immense amount of intelligent labor, and cannot fail to be a stimulus and benefit to the very wide-awake practitioners of the Lone Star State. The statistics show good, and even brilliant results in most lines of surgery. In amputations of the thigh the number of cases is 132, with 50 deaths; those of the leg are 166, with 27 deaths; those of the arm, 65, with 63 deaths; and those of the forearm, 66, with 2 deaths. These figures are even better than those, for example, of Max Schede, in which the operations are done with every possible antiseptic precaution. It must be remembered, however, that as the statistics collected by the Texas Committee are voluntarily contributed, it is quite possible that all the bad cases are not reported. The report shows that the Texas surgeon is quite able to cope with all varieties of surgery, even the most difficult.

ON FALSE LOCOMOTOR ATAXIA.

Locomotor ataxia is one of the best known of the chronic special diseases. It has indeed been so extensively written upon and so widely advertised that an undue tendency apparently exists to see locomotor ataxia in all cases showing ataxia and sensory symptoms.

Recent researches have shown that a good many cases showing the signs of locomotor ataxia were really not this disease, but were the result of poisons, of neuritis, or the indication of some brain disorder. Some of the apparent cures of locomotor ataxia are explained on this theory.

In a thesis for the doctorate in medicine (Paris, 1885), M. Leval-Picquechef has collected the numerous cases of false locomotor ataxia, or pseudo-tabes, and analyzed them. The results reveal in an interesting way the large number of causes, many of them quite common, which may produce a clinical picture a good deal like that of posterior spinal sclerosis.

The symptoms of locomotor ataxia have been produced by a sarcomatous tumor affecting the posterior spinal roots (Bennett), by small tubercular masses in the posterior columns (Topinard), by an arachnitis with a superficial marginal sclerosis of the cord (Ribail), and even by a diffuse sclerosis localized especially in the posterior columns. Posterior sclerosis is also produced by ergot poisoning and by pellagra. But apart from these, the symptoms of locomotor ataxia may be caused by various intoxicants, by infectious diseases, in diabetes, and in certain neurasthenic states.

Pseudo-tabes is produced as the result of alcoholic intoxication, and is one form of alcoholic paralysis. It occurs in adult life as the result of long-continued excesses in alcohol of any form, rum and brandy being the kinds most commonly used. It has been noted, so far, oftenest in England and Germany. It develops most frequently in women and in the better classes of society.

Lead in very rare cases causes a condition of pseudo-ataxia. The same occurs from poisoning by sulphide of carbon. Jaccoud, Berbes, and lately Ross, have mentioned instances in which workmen exposed to the vapor of this substance developed temporary ataxia.

Arsenic also has been known to cause pseudo-tabes, both when taken medicinally and even when absorbed into the system from poisonous wall-paper.

There seem to be hardly any of the severer infectious maladies which may not cause as a sequel the development of pseudo-tabes. The most frequent cause, however, is diphtheria. Of the eruptive fevers small-pox and measles have been followed by pseudo-tabes, while pneumonia, erysipelas, and typhoid fever have produced paralytic troubles closely resembling it.

It has for some time been known that in diabetes the knee-jerk is often abolished, and that the patient may suffer intensely from neuralgic pains. Very well-developed forms of pseudo-tabes have also been observed by Raymond, Dreyfus, and others. Since glycosuria sometimes appears in true tabes dorsalis, the diagnosis is not always easy.

American observers have asserted that pseudo-tabes may occur in cases of neurasthenia or spinal congestion. Dr. Leval-Picquechef cites an observation by Kowalensky on tabes dorsalis illusoria, and one by Huchard and Féré in support of this view.

In pseudo-tabes the cause of the symptoms is probably in almost all cases a multiple neuritis. The disease is characterized by its rapid evolution and in the complete

recovery which follows. The immobile pupil, disorders of the bladder, and rectal centres are not present, while there is usually some motor paralysis, which is not the case in true tabes.

CATHETERIZATION OF THE TRACHEA AND BRONCHUS.—Many will yet remember the fierce controversy in medical circles, raised by the late Dr. Horace Green, over the question of the direct medication of the trachea and bronchi, by carrying medicated solutions beyond the glottis. Dr. Green proved that it could be done, but his treatment was too heroic, and fell into disuse with the invention of powerful spray apparatus.

The discovery of cocaine took away the great practical obstacle to the application of this method, and of late it has been revived again by Reichert, of Rostock. This physician described his apparatus in the *Deutsches Archiv für klinische Medicin*, and showed it at the last meeting of the German Congress of Naturalists and Physicians. By its means he injected directly into the trachea and bronchi solutions of chloride of zinc, salicylic acid, menthol, and olei menth. pip. Dr. Schäffer, of Bremen, confirmed his results.

In are cent issue of the *Berliner klinische Wochenschrift*, No. 7, Dr. Landgraf, an assistant at Professor Gerhardt's clinic, describes an experience in the catheterization of the trachea which shows that this procedure is not difficult, and that it may have a considerable range of therapeutic usefulness. A man, fifty-two years of age, presented himself at the clinic suffering from symptoms of left-sided bronchial stenosis. He had attacks of coughing followed by dyspnœa of a severe character, and physical signs of interruption to the passage of air into the left lung. The man had had syphilis, and the diagnosis lay between a syphilitic gumma pressing on the bronchus and an aneurism. Antisyphilitic and all other treatment failed to make any impression on the symptoms. It was therefore finally decided to catheterize the trachea, and, if possible, the bronchus. The larynx was anæsthetized by pencilling it with a twenty per cent. solution of cocaine, and a ten per cent. solution of the same drug was sprayed into the trachea. A catheter was then introduced with the greatest ease, and was pushed down for the distance of 28.5 ctm. (over eleven inches), when an obstruction was felt. At a subsequent trial it passed the obstruction and was introduced for a distance of 32 to 36 ctm., measured from the incisors. This procedure was repeated several times weekly.

The relief caused was enormous. The patient had no more attacks for a month, and was rejoicing in his prospective recovery when an attack of unusual severity seized him and he died.

The autopsy showed the presence of an aneurism of the descending aorta compressing the left bronchus.

Dr. Landgraf thinks that though the relief caused by the catheterization was so temporary, it at least showed how well it is tolerated and how easily it may be carried out, and he suggests the wider extension of the practice of direct medication of the sub-laryngeal air-passages.

THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF TENNESSEE held its twelfth Annual Commencement on February 22d, and graduated a large class.

News of the Week.

THE IZARD COUNTY MEDICAL SOCIETY has condemned the present medical laws of Arkansas, and declares them to be a total failure, and declares that it will not accept the legal certificate of registration as any evidence of the physician's qualification to practise medicine.

A MEDICAL PROFESSOR WITHOUT SHAME.—According to the *Indiana Medical Journal*, the professor of surgical anatomy in a physio-medical college in Indianapolis announces in the daily papers that he possesses a remedy which "will cure membranous croup every time, and is the only thing that will." The formula is as follows :

Tr. sanguinaria	drachms iv.
Fl. ex. spikenard	drachms ij.
Oil pennyroyal	gtt. ij.
Simp. syr. (heavy).	q. s. ad ounces iv.

Mix.—Dose for a child of one year, ten drops, and add five more for each additional year. Give every half-hour, hour, or two hours, as the urgency may require.

THE SOCIAL AND POLITICAL ADVANCE OF THE PHYSICIAN.—The *Saturday Review* announces that the medical men of England are advancing in social position and political importance. This fact is indicated by the increasing number of physicians yearly commissioned as magistrates and elected to Parliament. *The Lancet* treats this information with a mixture of mild disdain and incredulity. To an American the social position of the average English doctor appears a very poor, not to say intolerable one, and if it is improving we are glad to hear of it. The English country doctor, however, is now more highly esteemed, not, as it seems, because he knows more, but because, owing to the extension of the franchise, "he has come into the possession of political power."

MANHATTAN EYE AND EAR HOSPITAL VERSUS MANHATTAN HOSPITAL.—The General Term of the Supreme Court has ordered unanimously that the so-called Man hattan Hospital, in Manhattanville, formerly the Manhattan Dispensary, shall not use its name of Hospital, because there is danger of confusion arising from the use of the two names, Manhattan Hospital and Manhattan Eye and Ear Hospital.

THE LONDON THROAT HOSPITAL, for diseases of the throat, nose, and ear, was opened on February 14th last, at 204 Great Portland Street, W., under the general supervision of a General Committee, associated with an Executive Committee which shall include the medical staff that will preside over the management of the hospital directly. The promoters of this hospital were lately members of the medical staff of the Hospital for Diseases of the Throat, Golden Square, where they served as medical officers and teachers for many years. The chief object of this institution will be the free treatment of the sick and necessitous poor, and it will be the aim of the management to avoid a system of pauperizing the people, by requiring small weekly payments from those patients whose earnings will enable them to contribute toward the hospital expenses. At the head of the medi-

cal staff stands the name of W. McNeill Whistler, M.D., M.R.C.P., well known here, not only from the fact that he was born in the United States, but because of his meritorious writings on the special diseases in which he has made himself an authority. Among his associates is Edward Woakes, M.D., whose writings on diseases of the ear are also well known. The medical staff has seven members.

A Medical Microscopical Society in Brooklyn.—A meeting of Brooklyn physicians interested in microscopy was held at the house of Dr. Herbert Fearn, 196 Clermont Avenue, Brooklyn, on Wednesday evening, February 16, 1887, for the purpose of organizing as the Medical Microscopical Society of the City of Brooklyn. The specific object of this society will be the consideration of medical microscopy. Meetings will be held on the first Wednesday evening of each month. The following officers were elected: William H. Bates, M.D., President; Arnold Stub, M.D., Vice-President; Frank M. Hoyt, M.D., Secretary; Henry D. Bliss, M.D., Corresponding Secretary; Albert Brinkman, M.D., Treasurer.

This is the Season when the history of medicine is reviewed from the earliest time to the present day by eloquent commencement-orators. It is a period when thousands are refreshed with the story that medicine is the noblest and grandest of professions, and when the young medical graduate is surprised by being told that he is just on the threshold of a new career in which he is destined to hush the groans of millions with the joy of health.

An Opinion on Dr. Mathews Duncan.—Mr. Tait, writing to the *British Medical Journal* regarding the Liverpool Hospital quarrel, says of Dr. Duncan, what we believe is more of a compliment than he intends. He says of him: "Dr. Duncan's views are warped by a belief which I respect as honest, but regard as wholly mistaken and most unfortunate for 'good gynecology.' This belief is to the effect that the majority of women who give a detailed, sequent, and consistent story of pelvic suffering, 'have nothing the matter with them.' This has passed into a by-word, and has immensely diminished Dr. Duncan's sphere of usefulness in the practice of medicine." We venture to say that Dr. Duncan holds no such extreme view as represented, and that if gynecologists with pet operations dominating their minds were to absorb a little of Dr. Duncan's conservatism their sphere of usefulness would be greatly enlarged.

The Fifty-fifth Annual Meeting of the British Medical Association will be held in Dublin on August 2, 3, 4, and 5, 1887, under the presidency of Dr. Withers Moore. An address in medicine will be delivered by W. T. Gairdner, M.D., F.R.C.P.Ed. An address in surgery will be delivered by Edward Hamilton, M.D. An address in public medicine will be given by the Rev. S. Haughton, M.D., F.R.S., D.C.L.

Physicians Intending to be Present at the International Congress.—Among the list of gentlemen announced by Dr. D. J. Hamilton as intending to be present at the International Congress, we find among surgeons: Mr. T. Bryant, Mr. C. Heath, and Mr. Jonathan Hutchinson, of England. Among gynecologists and obstetricians: Mr. Lawson Tait, of England; Professor Gustav Braun, of Vienna; Professor Hegar, of Freiburg; J. Amédée Doleris, of Paris. Among neurologists and alienists: Drs. J. Althaus, G. H. Savage, D. Hack Tuke, D. Ferrier, H. C. Bastian, Sir J. C. Brown, William J. Mickle; A. Eulenburg, of Berlin. Among dermatologists: Dr. George Thin, of London; Hans von Hebra, Neumann, and Kaposi, of Vienna; P. E. Unna, of Berlin. Among general physicians: Drs. B. W. Richardson, Charles West, Eustace Smith, George Johnson, Sir E. Sieveking, N. T. H. Waters, J. S. Bristowe, Pye-Smith, of England; Professor Dujardin-Beaumetz, of Paris; Drs. Lewin, Gusserow, and Veit, of Berlin. Chiari, of Vienna, is also down as intending to be present.

French Surgical Congress.—The third meeting of the French Surgical Congress will take place in Paris in April, 1888, at a date which will be announced shortly, under the presidency of Professor Verneuil. The following questions are arranged for debate at the Congress: 1, On the Treatment of Gunshot Wounds of the Visceral Cavities; 2, On the Value of the Radical Treatment of Hernia as a Permanent Cure; 3, Chronic Suppuration of the Pleura, and its Operative Treatment; 4, Recurrence of Tumors after Operation (Causes and Prevention).

The Antiseptic Treatment of Summer Diarrhœa.—In an article on the above subject in the New York *Medical Journal*, Dr. L. Emmet Holt claims superiority for the antiseptic method of treating diarrhœa, and recommends especially salicylate of soda and naphthalin in the disease. There appears to be something of a *non sequitur* in the conclusions, since salicylate of soda is not especially antiseptic, ranking very low in Miguel's scale.

Changes in the Professorial Staff of the Paris School of Medicine.—M. Dieulafoy, Professor Agrégé at the Paris Medical Faculty, has been elected Professor of Medicine in place of M. Peter, who is appointed to another chair. M. Farabœuf, Director of the Practical School of Dissection, has been chosen to succeed M. Sappey in the Chair of Anatomy. M. Gariel, Professor of Medical Physics, has been appointed to the Chair of Physics in place of M. Gavarret. A law recently passed ordains that no professor of medicine shall continue in office after the age of seventy. MM. Sappey and Gavarret have attained that age. M. Pajot, in terminating his course of lectures at the Clinique de la Faculté de Médecine, announced that he preferred retiring from office before reaching the age of seventy. In the midst of the applause which followed M. Pajot's speech, a curtain was drawn aside, and a bust of the Professor placed on a pedestal, draped in velvet and gold, was discovered. M. Peyron, Director of the Assistance Publique, then came forward to thank M. Pajot, in the name of the poor of Paris, for the devoted kindness which he had shown toward them for forty-five years.

The Physiology of Opium-narcosis.—M. Liebermann, in a monograph upon opium-smoking, states the conclusion that the deep narcotic sleep of opium is due to severe cerebral congestion.

Rush Medical College held its forty-third Annual Commencement on February 15th and graduated one hundred and thirty-four students.

The Medical Association of Georgia meets at Atlanta on April 20th.

The Medical Department of the University of Louisville held its fiftieth Annual Commencement on March 1st. Its graduating class numbered eighty-seven.

The New York City Board of Health.—The appointment of Mr. James C. Bayles as President of the Health Board has met the general approbation of non-partisan citizens. Mr. Bayles is a sanitarian and not a politician.

Bellevue Hospital Medical College.—The twenty-sixth Annual Commencement of this college was held on Thursday last, when a class of one hundred and thirty-four was graduated. The exercises were pleasantly varied by an adjournment to Delmonico's, where a supper was served and speeches made.

Sewer-gas and Malaria are said to pervade the chambers of our multiple-million-dollar Capitol at Albany.

Died from Diphtheria.—Dr. E. L. Andrews, a young physician of West Farms, N. Y., died last week of diphtheria contracted from a patient. We have recently learned of three physicians of this city who suffered from diphtheria contracted in their practice, but who have fortunately recovered.

Vaccination against Snake-bites.—Professor Sewell, at the University of Michigan, Ann Arbor, has been carrying out some experiments in Pasteurization, taking for his subject the virus from the sacs of rattlesnakes. By attenuation and cultivation he has succeeded in protecting pigeons and rabbits by inoculation, so that they will withstand inoculation of five or six times the strength of uninoculated pigeons or rabbits.

The International Congress.—Mr. Lawson Tait has been elected one of the Vice-Presidents of the International Congress. We learn that Congress appropriated $10,000 for the International Medical Congress.

The Bequest of a Medical Editor.—The late Dr. Wakley, editor of *The Lancet*, has bequeathed to the University College Hospital of London, for and on behalf of the Hospital, his freehold residence, Heathlands, Longcross, Chertsey, and eight acres of land, for the purposes of a convalescent home for patients from this hospital, as a memorial of his late father, Thomas Wakley, Esq., M.P., the founder of *The Lancet*, the home to be called the "Wakley Convalescent Home." He also bequeathed £1,000 to be expended in the maintenance of the convalescent home, at the rate of £200 per annum.

Beriberi on the Isthmus of Panama.—A case of beriberi, originating at Panama, has been observed in Paris by Dr. P. Marie.

The Results of New York City Baby-farming.—The city has been trying the experiment of putting the infants brought to Randall's Island Hospital out at various homes in the country at Mount Vernon. Fifty or sixty infants are being cared for in this way; so far, with a reduction of mortality from thirty to about five per cent.

Prosecuted for Skin-grafting.—An extraordinary case of prosecution and persecution has recently occurred in the Atlanta, Ga., courts (*Atlanta Med. and Surg. Journal*). On August 30, 1886, in the presence of Drs. Hardon, Westmoreland, and Howell, Dr. Henry Wile, of that city, proposed to a boy of thirteen years to submit to the removal of some small skin-grafts from his arm to be placed upon an extensive ulcerated surface on the head of his cousin, a little girl somewhat younger, whom he had accompanied to the office. The boy readily consented, and minute grafts were excised without causing him any inconvenience. In the afternoon of the same day the father of the boy went to the office and charged Dr. Wile with having cut "his son's arm to pieces." He subsequently swore out a warrant charging him with assault and battery. Upon trial the case was promptly decided in favor of Dr. Wile.

The Late Professor Schroeder died of a cerebral abscess. It was well circumscribed and might have been reached and opened by a surgical operation, but the combined skill of Berlin's best physicians, including Professors Westphal, Gerhardt, Leyden, and von Bergmann, could not reach a positive diagnosis. Professor Schroeder six years ago had an attack of ophthalmia and erysipelas from a septic matter which got in his eye. He recovered, but from that time, however, he had been subject to attacks of giddiness and syncope, which were attributed to weakness of the heart. Last winter he was again attacked with serious illness, and he was sent to Nice. In November last year threatening symptoms again made their appearance, but he rallied, until fourteen days before his death symptoms of serious brain disease confined him to his bed. The diagnosis lay between cerebral abscess, cerebral tumor, and meningitis, but no nearer decision could be reached. Death occurred and the autopsy was conducted by Professor Virchow, and reported on by him before the Berlin Medical Society on the 9th ult. In the posterior part of the right cerebral hemisphere was an encapsuled abscess, about the size of a walnut. This had broken through toward the right ventricle, causing sharp hemorrhage and acute inflammation. In the mediastinum, also, near the right lung and the œsophagus, remains of a smaller abscess were found. No other trace of disease was discoverable.

The Public Meeting for the Purpose of Raising Funds for a building for the Woman's Medical College of the New York Infirmary, held on Monday last, was well attended and was successful in every particular. Already the sum of $15,000 has been subscribed.

The Journal of Laryngology and Rhinology is the title of a new monthly devoted to the specialty indicated by the title. It is edited by Dr. Morell Mackenzie and Dr. R. Norris Wolfenden. The first number, published in January, makes a very creditable appearance, both as regards contents and mechanical make-up. We extend our welcome to this new aspirant for professional favor.

The "Sacramento Medical Times" is the title of a new medical monthly published at Sacramento, Cal., and edited by James H. Parkinson, L.R.C.S.I. Sacramento has not been much heard of in medical circles, and we are glad to find that it is to have an organ

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 3, 1887.

CHARLES CARROLL LEE, M.D., VICE-PRESIDENT, IN THE CHAIR.

DR. WM. H. THOMSON read a paper on

THE PATHOLOGY AND TREATMENT OF EPILEPSY,

based on notes of sixty consecutive cases in private practice. The definition of a disease should include the most invariable features of the affection; the essential must never fail to be present. He did not consider epilepsy as necessarily a convulsive disorder. He gave the following definition:

Epilepsy is a disease characterized by sudden and temporary loss of function on the part of one or more cerebral centres, an attack being induced by an afferent impression in every case.

The essential and invariable element in epilepsy is suddenness. It is the single truly sudden disease. Other diseases may be rapid in their attack, but never sudden in the sense that epilepsy is. Among the neuralgias, angina pectoris may be an exception. Therefore all recurrent symptoms, whether sensory or motor, which are characterized by suddenness are ominous, because suggestive of epilepsy. Consequently *petit mal* was more real, as well as more objectionable, than *grand mal*.

Dr. Thomson then reviewed some of the theories that have been advanced with reference to epilepsy, as Hughlings Jackson's theory of the explosive discharge of nerve-cells from increased functional activity or increased nutrition; disturbance of Nothnagel's convulsive centre in the medulla; Robertson's upward discharge from this centre; Gowers' involved theory, etc. The conclusion reached was, that all normal motor phenomena, except the purely voluntary, were directly regulated by the sensory department of the nervous system in all those respects which imply regulation of degree of the motor forces and regulation of the time of their liberation and the channels through which these are liberated, whether singly or co-ordinated.

Given a moderate restraint of nerve-cells and -centres by each other, and we have the status of bricks in an arch; but withdraw one brick and the arch may behave as if shaken by an earthquake, when the disturbance all came from the sudden loss of the function of one brick.

The objection to the explosive sensory-motor theory was that it required more than one mechanism for the production of the same effect. The answer to the claim that Hitzig has produced epilepsy by limited motor excitation alone, and that it has been caused by irritation of the cortical motor area alone, etc., was that we do not get rid of the sensory-motor relations when the cranium is entered.

As to the *treatment of epilepsy*, Dr. Thomson emphasized the great importance of *perseverance*, for many obstinate cases had finally yielded. The first indication was to *improve nerve-nutrition*, and the most efficient agent that could be employed for this purpose was *cod-liver oil*. The prophylactic influence of this remedy was very noteworthy with reference to nervous diseases occurring in neurotic families, and particularly epilepsy.

The next remedy recommended for nerve-nutrition was *phosphorus;* the syrup of the hypophosphites (U. S.) acidulated by the addition of one-fifth part of dilute phosphoric acid.

Total exclusion of butcher's meat for two years should be insisted upon; animal diet predisposes to convulsions and convulsive diseases.

Check rapid eating, because of the liability to irritate the convulsive centre in the medulla through the influence of crossing nerve-fibres.

The *bromides* are the most efficient remedial agents for the control of the attacks. These are to be aided by remedies which prevent them from impoverishing the blood, and they may be assisted very materially in producing their peripheral action by the use of the *red-pepper or mustard pack* before going to bed. Add a teaspoonful of red pepper to a pint of hot water, and wrap the body in flannel wet with a solution of this strength.

When muscular twitchings of the face occur during sleep, he regarded them as evidence of persistent cortical irritation, and advised the use of corrosive sublimate in doses of $\frac{1}{24}$ of a grain.

When symptoms referable to the digestive tract were present, *belladonna* with *oxide* of *zinc* should be used, pushing the belladonna to the production of its physiological effects.

When foul breath accompanies the gastric disturbance, *resin* of *turpentine* should be given as an antiseptic with belladonna.

The continuous use of *chloral hydrate* was beneficial. *Digitalis* was indicated when epilepsy was characterized by symptoms belonging to the genito-urinary tract, or by vascular symptoms.

The discussion was opened by DR. L. PUTZEL, who, from a clinical stand-point, thought that the claim that epileptic attacks were always sudden could not be sustained, as it was not at all infrequent for prodromata, gastro-intestinal, mental, or otherwise, to precede the outbreak for two or three days. The suddenness of the attack could not be regarded as characteristic and the essential of epilepsy.

He had always understood that Jackson's theory referred to the explosive discharge of nerve-cells, not implying that it is limited to the motor nerve-cells. According to Jackson the visual disturbances in migraine are really epileptiform, and he claims that migraine belongs to that class of disorders. This proves that he does not limit the explosive discharge to the motor cells. Furthermore, Dr. Putzel could not understand what there was that led Dr. Thomson to believe that sensory impulses inhibit motor impulses; for a sensory impulse is generally a stimulus that sets a motor impulse into activity.

He thought that the paralytic attacks of *petit mal* were rare. The paralytic conditions were usually seen after severe motor convulsions, and were then probably due to exhaustion.

The pleural epilepsy which had been referred to by Dr. Thomson, produced by injections into the pleural cavity, did not strike him as valuable for the purposes of argument, because there was nothing to prove that the convulsions were epileptic. He did not think that the single manifestation of anything was epileptic; it was epileptiform, but not until it had been developed several times could it be regarded as true epilepsy. Convulsions from teething, which were probably due to local irritation, were not epileptic, but epileptiform, although the mechanism was probably similar to true epileptic attacks. In the one, however, there was a purely local lesion, which gave rise to reflex action by general brain-discharge; while there was in the other case some unknown condition of the brain itself, probably in the higher centres, which was the fundamental lesion—if what cannot be seen may be called a lesion—of epilepsy.

With regard to belladonna, he had used it in nocturnal epilepsy chiefly, in conjunction with the bromides. He agreed with Dr. Thomson that the disease was one of impaired nutrition, and therefore he prescribed cod-liver oil.

DR. PUTNAM-JACOBI referred to the question of rapid mastication, in connection with Lauder Brunton's directions that the fainting person be induced to sip cold water for the purpose of arousing him from syncope. According to Gowers the aura, in about one-fifth of the cases of epilepsy, is of the special senses, which indicates that the lesion is cortical. The statement made by Dr.

Putzel concerning paralytic conditions seemed to be contradicted by Gowers, who cites one or two cases in which there was a sudden loss of motor power.

Dr. W. H. Draper said that he had listened to Dr. Thomson's paper with much pleasure, though he could not say that the author had thrown much light on an obscure subject by his ingenious theory, or that he had seriously shaken existing hypotheses as to the pathology of epilepsy. He believed that it was generally admitted that a large proportion of attacks probably had their origin in the convulsive centres of the cerebral hemispheres, and it was thus easy to account for the temporary aphasia and other transient psychical and sensory auras which sometimes preceded or even occurred without the motor discharge.

The question of the determining cause of the phenomena of an epileptic attack, whether it is the result of vaso-motor spasm or not, is still undecided; and Dr. Thomson's hypothesis that it is a withdrawal of the control which the sensory functions of the nervous system exert over the motor functions does not appear to make the cause more clear. Dr. Draper agreed with Dr. Putzel in believing that it was not right to regard convulsions of peripheral origin, like the convulsions of dentition and gastro-intestinal irritation, as the exact parallel, pathologically, of idiopathic epilepsy, except in so far as they might both involve a sensory cause. He cordially concurred in what Dr. Thomson had said in regard to the treatment of epilepsy, and especially as to the importance of improving the nutrition of the nervous centres by cod-liver oil and tonics. He thought that, next to this, the most important point in the management of the disease was a careful study of the possible peripheral irritations which might provoke the attacks. These were very often found in errors of diet. He could not agree with Dr. Thomson, however, in what he had said about the exclusion of animal food from the diet of epileptics. On the contrary, he had been inclined to believe that the gastro-intestinal irritations which were the exciting causes of epileptic seizures were much more likely to follow the indigestions caused by overfeeding with the carbo-hydrates and fermented liquors. He preferred a diet of milk and animal foods for his patients, and had had excellent success in diminishing the frequency of the seizures by regulating the diet upon this principle. The next important point in the treatment of the disease was, of course, the administration of some drug which would diminish the extreme irritability of the convulsive centres; for this purpose no remedy had yet been discovered which equalled in certainty and in power the potassic bromide. Yet, despite all these measures, the experience of every physician would recall cases in which every form of treatment failed to control the disease, cases in which the patients preferred to have their fits rather than suffer the self-denials imposed by dietetic restrictions, and especially the misery of mental and physical hebetude caused by large doses of the bromides.

Dr. E. D. Hudson thought that the most plausible explanation of an epileptic attack was found in an initial condition of cerebral anæmia, due to spasmodic contraction of the cerebral vessels, that gives rise to disturbance of the equilibrium of the nerve-force. He believed that convulsive attacks might become true epilepsy if allowed to persist. The best remedies at our command are the bromides.

Dr. Thomson said he never intended to imply that epileptic attacks had no prodromata. But a prodroma was not an attack. His reference was to the actual steps in the attack, and in those epilepsy was to be distinguished from all other diseases by its suddenness.

With regard to Hughlings Jackson's theory, he would say that he had understood that, while its author does not refer to motor discharge only, he specially dwells upon the motor discharge as the cause of the convulsive attack.

As to a sensory influence being stimulating in character, he should regard it as regulating the character by some kind of withdrawal or directing of motor impulse.

With reference to confounding all convulsions with epilepsy, his own observations had led him to the conclusion that he was unable to distinguish between convulsions of epilepsy in children and epileptic attacks occurring in dentition. He would be exceedingly obliged if either Dr. Putzel or Dr. Draper would tell him what an epileptiform convulsion was.

Dr. Draper said that, in saying that a convulsion was epileptiform, he simply conveyed the idea that it had the form of epilepsy, but not the substance or nature of it. He thought there was an essential difference between epilepsy in its most aggravated form and an epileptiform spasm as the result of either extreme peripheral irritation or extreme central excitability.

Dr. A. D. Rockwell then read a paper on

THE VALUE OF ELECTRICITY IN THE TREATMENT OF EPILEPSY,

in which he said that, if he were asked whether, under any circumstances, electricity alone was capable of curing epilepsy, his answer necessarily would be, exceedingly doubtful. Although he had never heard of a case that had been cured by electricity, he was not prepared, by any means, to say that such a result was impossible, or even highly improbable. If, however, he should be asked whether or not electricity was of any value in the treatment of epilepsy, he would unhesitatingly and confidently say that it was. He felt warranted, from his own experience, in going even further than that, and was willing to say that in a certain proportion of cases in which the patients fail to receive more than temporary benefit from the bromides they may recover entirely when this plan of treatment is re-enforced by the judicious and persistent application of electricity. What this proportion is must be a question for further and more general investigation.

Epilepsy is not, like chorea, frequently self-curative, and the books and journals say that benefit attends the use of a score or more of different remedies. Many of them are undoubtedly of value in treating the disease, and in some cases effect an absolute cure. Electricity has been found to act favorably upon the epileptic seizures; but what should more especially entitle it to consideration was its peculiar efficacy associated with other and more generally approved remedies, after these remedies alone had failed to give more than temporary relief.

The suggestion that the best results will be obtained in the treatment of epilepsy only when we call to our aid every measure that tends to develop vital power is one which commends itself to all. It is not alone, therefore, on the theory of the special influence on the nervous centres, or on cerebral circulation, that we employ electricity as an adjuvant to the bromides, but also because of its undoubted powerful constitutional effects. Above all, it is a *tonic*, and yet its therapeutical range is sufficiently wide to include both stimulating and sedative effects.

Therapeutically speaking, there are indications for the use of electricity in epilepsy other than those which call for its general tonic influence or its effects on the circulation.

An important indication for its use is the hyperexcitability of the nerve-cells in epilepsy. By submitting theoretical considerations to practical tests he had been convinced that this hyperexcitability, in some cases, has been held in check by the action of the galvanic current as readily as by the bromides. In several cases of *petit mal*, especially, he had observed that applications of the galvanic current to the cervical ganglia of the sympathetic produced precisely the same effect, in interrupting temporarily the frequency of the paroxysms, as did the bromide of potassium.

An illustrative case was cited, in which treatment, electrical and medicinal, was persevered in for fifteen years, and up to this date, nearly four years from the last epileptic seizure, the patient—a woman who was twenty-six years of age when the first attack occurred—had been entirely free from even a suggestion of epilepsy. From being hysterical, passionately unreasonable, and personally unattractive, the graces characteristic of the best feminine type had been either restored or come as a new growth. Three other cases also were reported, in which electricity, combined with other measures, had produced markedly good results.

Dr. Rockwell then presented the unsatisfactory side of the picture. The total number of cases of epilepsy which he had treated, with especial reference to the value of electricity, since 1874 was twenty-eight. All were in private patients. Ten abandoned treatment too quickly to be worthy of the slightest consideration in a statistical estimate of the value of any remedy. In three cases the treatment was persisted in sufficiently long to enable him to give electricity a fair trial, and he was compelled to admit that it seemed in no way to aid the bromides in controlling the disease. It was to be noted that in two of these three cases the seizure occurred in the daytime and while awake, and in the other the attacks took place both night and day.

Eight other cases, of which he had records, were under observation from six weeks to nine months. In all of them good effects of the treatment were manifest in a greater or less degree; and in two of them, one of which was under observation seven and the other nine months, the notable improvement was unquestionably due, in part at least, to electricity. Four of the remaining seven cases appeared in the present paper, and the others had been recorded in THE MEDICAL RECORD, April 6, 1878.

The conclusions which Dr. Rockwell had reached, after making observations for thirteen years, were :

First.—Electricity possesses a certain value in the treatment of epilepsy. It is not known, nor is it claimed, that used alone it can ever cure epilepsy. When, however, it is used in connection with the bromides its value is unmistakable, and a certain number of patients recover who otherwise would remain uncured.

Second.—The good effects of electricity are seen especially in cases in which the attacks occur in the night, although day attacks have been successfully controlled.

Third.—Central galvanization and general faradization have been the most efficacious methods employed.

Fourth.—When electricity fails to either cure or aid the cure, it is often efficacious, by the method of general galvanization, in affording grateful relief from undefinable nervous symptoms recognized under the term neurasthenia.

Fifth.—The tolerance of bromides can be increased and bromic acne diminished by the systematic use of electricity.

Sixth.—Electrical treatment must be administered with care and judgment. All interruptions of the current should be avoided in central galvanization, as the shock is liable to hasten rather than prevent an attack.

DR. W. H. THOMSON said that he had not had any experience in the use of electricity in the treatment of epilepsy, but he could understand that it might be serviceable as a peripheral irritant, the same as the mustard-pack.

DR. E. D. FISHER had not used electricity for the purpose indicated, but the principle of peripheral irritation would be that upon which he would employ it.

DR. ROCKWELL said that he did not lay very much stress upon the peripheral irritation, for to produce that the faradic current should be used. The galvanic current was what he had relied upon, on account of its influence on the nerve-centres, and it does not apply to the periphery.

The Academy then adjourned.

SECTION IN OBSTETRICS.

Stated Meeting, February 24, 1887.

E. L. PARTRIDGE, M.D., CHAIRMAN.

DR. MALCOLM MCLEAN read a paper on

RUPTURE OF THE UTERUS,

in which he analyzed the subject with special reference to the performance of laparotomy.

What shall be done to save the life of the woman when rupture of the uterus occurs? This question had been discussed by many, and among them Dr. Harris, of Philadelphia, in a paper published six years ago; and the answer was, practically, to open the abdomen as promptly as possible, whether the child has been delivered or not. The performance of laparotomy was the key-note to the radical treatment of this accident.

Dr. McLean then studied the etiology, the pathological anatomy, the symptomatology, the diagnosis, the prognosis, and the treatment of rupture of the uterus, occurring at full term of pregnancy or during labor. He was inclined to place the frequency of its occurrence at a higher figure than Dr. Harris had, who recorded it as one in four thousand, and he did this because he believed that rupture occurred in a considerable number of cases in which it was either unrecognized or was never made known. In other words, he believed that its occurrence was more frequent than the statistics of published cases would lead us to believe. The majority of cases occurred in primiparæ. He had met with two traumatic and two spontaneous ruptures. It occurred most frequently at the junction of the body and the neck.

The characteristic symptoms were sudden cessation of labor pains, recession of the presenting part, shock, external hemorrhage, and the presence of the fœtus in the abdominal cavity.

Dr. McLean gave the details of his cases, in one of which recovery took place. There was sudden cessation of pain, he prepared to deliver with the forceps immediately, but found that the head had receded, and he then introduced his hand into the uterus, when he found that the child had escaped, except the head and one arm. He seized the head, and, with only a moderate amount of traction, was able to draw the child back so that he could grasp one thigh, when he performed version and delivered rapidly. He then delivered the placenta. The uterus contracted readily and firmly. The laceration was probably subperitoneal. The shock was slight. A large hæmatocele quickly formed upon the right side of the uterus. Thorough antiseptic treatment was instituted and maintained, and the woman finally made a good recovery.

The author of the paper then addressed himself to the consideration of the question, What shall be done to save the woman's life when rupture of the uterus has taken place? At this point special reference was made to the recent discussion held in the London Obstetrical Society, the general tenor of which was that, under all circumstances, it was advisable to perform laparotomy, even though afterward the child was delivered through the natural passages.

While Dr. McLean believed that there were many cases in which laparotomy was the operation that should be performed, he also believed that delivery through the natural passages should not be thrown out of consideration entirely, and that in cases of incomplete rupture delivery by the vagina should be attempted, even if it became necessary to perform laparotomy afterward.

In cases in which rupture occurred before dilatation of the os was complete, or in which liquor amnii had escaped into the peritoneal cavity, or in which loops of intestine had entered the uterine cavity, etc., we should be ready to perform laparotomy, and, under some circumstances, Porro's operation. Dr. McLean pre-

sented the specimen, from one of his cases, in which the placenta was found hanging in the rent.

Dr. C. C. Lee was invited to open the discussion, and said that he thoroughly agreed with the spirit underlying Dr. McLean's paper, in which he had taken the position, if he had understood him correctly, that, given a case of rupture of the uterus, it was best to assume it to be incomplete until proved to be complete, and that it was better, if the membranes be intact, not only to attempt to deliver through the natural passages, but to persist in the effort rather than expose the woman to the additional shock incident to laparotomy. But, judging from his limited personal experience and from the experience of others, he should think that Dr. McLean's successful case was a very remarkable one indeed, and that his views would apply to an extremely small number of cases. He believed that as rupture of the uterus occurred in actual practice, the procedure adopted by Dr. McLean in his case would be almost impossible. There was no doubt that, when the woman was suffering from shock, the additional shock from opening the abdominal cavity was terrible to assume. But, when death was so nearly certain as it was under these circumstances, desperate measures were justifiable and demanded.

When the head cannot be reached readily with the forceps, or version cannot be performed promptly, he believed that more harm would be done by persistence in these operations than would come from laparotomy. Dr. Lee then referred to two reported cases in which laparotomy was performed successfully under very unfavorable circumstances.

If the patient was *in articulo mortis*, he thought that most surgeons now would attempt to deliver the child in a manner different from that indicated by Dr. McLean, and he could not share in the deprecation which the author of the paper had brought against the plan of treatment generally approved of in this and other countries.

Dr. W. T. Lusk continued the discussion, and said that he had seen three cases of spontaneous rupture of the uterus. In the first the child did not escape into the abdominal cavity, and delivery was accomplished with the forceps. The woman died within twenty-four hours. He thought that, in this case, it would not have been of much service to have performed laparotomy. On the other hand, laparotomy would not have contributed toward the death of the woman.

In the second case he made a fatal mistake. He went to the hospital and saw the woman, who had been brought in from the street, and she was in excellent condition. Labor, however, did not progress. The child did not escape into the abdominal cavity, and it was delivered by version. The woman had a good pulse after delivery, and everything seemed to be in her favor. But she died within twenty-four or thirty-six hours, and at the autopsy her abdominal cavity was found filled with blood. Dr. Lusk believed that, with all the favorable conditions, if he had opened the abdomen and sutured the uterus—certainly, if it could have been sutured as it would be to-day—the woman's life would have been saved.

In the third case the accident was not recognized during life. The rupture did not extend through the peritoneum. An immense hæmatoma formed, and from this death occurred by septicæmia. In this case, had the condition been recognized early enough, removal of the cloths and introduction of a bent drainage-tube might possibly have saved the life of the patient.

He did not think that there was a great deal of relevancy in discussing the question of laparotomy when the child had partially escaped from the uterus. For the one thing which it was desirable to avoid was enlarging the rent in the uterine wall, and additional rupture would almost certainly occur in attempts to effect delivery by the vagina. Under such circumstances, then, it was preferable to make the abdominal section. Even if only a part of the child had escaped, and it could be readily delivered and the mother was in good condition, he should feel better after he had made the abdominal section and closed the rent in the uterus than he would to leave it practically to nature. Still, there were eight or ten cases on record which sustained the view set forth by Dr. McLean. These had occurred since the advent of Felsenreich's bent drainage-tube.

Dr. H. T. Hanks thought that when one fact was considered in Dr. McLean's case, it would not seem so surprising that the woman recovered, and that fact should always be before us, namely, that the rent in the uterus *closed quickly after the child was delivered.* The uterus was not prevented from contracting. But had it been like a case in his own experience, where there was no contraction of the rent about his hand, he would not expect that the woman would get well.

Given a ruptured uterus, the child in the abdominal cavity, the membranes ruptured, the rent so large that the uterus would not contract fully and thoroughly, there would be great danger in allowing it to remain without operative interference. But if the rent was low down and the fœtus dissected for itself a cavity, as it were, by pushing up the peritoneum, the probabilities were that the woman might recover.

In the great majority of cases of rupture of the uterus the woman will die if treated in the old way. Hence if the rent was large and the child was in the abdominal cavity, he would perform abdominal section and suture the uterus, or, if necessary, perform Porro's operation.

Dr. E. H. Grandin said he had thought that, should he meet with a case of rupture of the uterus, he would do just what Dr. McLean did, and try to deliver by the natural passages, and, if he did not succeed, he would, in accordance with the teachings of those who have had experience, resort at once to laparotomy, as he would in the presence of symptoms suggesting abdominal hemorrhage. He could not help thinking, however, that Dr. McLean's success in his case was exceptional. If the uterine suture could not be used, he would perform Porro's operation.

Dr. Boldt had had one fatal case of rupture of the uterus. He favored laparotomy when the rent was large or was high up, provided the woman was not suffering from shock.

The Chairman had seen two cases, in both of which laparotomy was performed, and both terminated fatally. The operations were performed under reasonably favorable circumstances, although there was considerable shock and evidence of extensive hemorrhage. One woman lived three days, and died of peritonitis; the other lived more than twenty-four hours, and died of shock. Dr. McLean had brought out an important point when he spoke of too prolonged use of the forceps. He regarded liquor amnii as far more irritating than blood, although, of course, it was not desirable to have blood enter the peritoneal cavity. It did not seem to him that the condition of shock need be considered very much as a contra-indication to laparotomy, for laparotomy could not add very much to it in most cases.

Dr. McLean had been very much interested in the discussion, particularly as it had appeared that his sentiments had not been understood fully. He had intended to use language which was so plain that it could not be misunderstood. Dr. Boldt had assumed that his paper was a protest against laparotomy, whereas he wished to protect the woman from unnecessary laparotomy and to give her its full benefit in all cases where it was required. He argued in favor of delivery through the natural passages because of the growing tendency of modern discussion to rule out of consideration all such interference. The London Obstetrical Society, composed of representative men, had given its support to the doctrine that it would be malpractice to attempt to deliver through the natural passages, even if the child was small, had not entered the peritoneal cavity at all, and the rupture was incomplete; but that laparotomy should be performed

under all circumstances, even if afterward delivery of the child was effected through the vagina.

He had simply wished to reverse the argument, and would say that, if we could, we should deliver the child by the natural passages, even if we had to perform laparotomy afterward.

There were cases in which rupture occurred before dilatation of the os had taken place, or in which there would evidently be great difficulty in effecting delivery, or the intestines were in the uterine wound, or there was evidence that liquor amnii had escaped into the peritoneal cavity, etc., and in such cases we should be ready to perform laparotomy, and, under some circumstances, Porro's operation.

But, in cases of rupture of the uterus in which the peritoneal cavity was not invaded, and in which the early operation of delivery through the natural passages could be done under thorough antiseptic precautions, he believed that this method gave fully as good opportunity for the woman to recover as did laparotomy; indeed, better. If the membranes were intact, except at the point where their original rupture was, it was evidence that the peritoneal cavity had not been invaded by anything except blood, and under those circumstances he did not believe that it was desirable to open the abdomen.

The Section then adjourned.

Correspondence.

A COUNTRY DOCTOR OF A HUNDRED YEARS AGO.

To the Editor of The Medical Record.

Sir: In the spring of 1773 Dr. Samuel White began practice in the infant town of Newbury, Vt. He was twenty-three years of age, but had devoted already six years to preparation for his life-work. He had received a common school education, some instruction in Latin, and had spent four years under the tuition of Thomas Brickett, M.D., at Haverhill, Mass. He had practised nearly two years in his native village of Plaistow, N. H., before he was influenced by friends to join them at Newbury. Only rough outlines remain of the heroic and adventurous side of his long, active, honored life. His own records suggest a little, the private journal of a contemporary tells more, and imagination can fill in many details. From Newbury to Canada, along the Connecticut River, he was for many years "the doctor," and his practice extended widely on either side. He visited in Corinth, Bath, Haverhill, Newbury, Mooretown (Bradford), Barnet, Piermont, Upper Coos, Lyman, Peacham, Ryegate, Topsham, Gunthwaite (Littleton), Landaff, Morristown, Apthorpe (Lisbon), Wentworth, Coventry, Rumney, Groton, and Riverlamoile. He travelled often, in the winter, upon snow-shoes, crossed unbridged streams, made his way through uncut forests and roadless wildernesses. He responded always to the call of the poor, and gave freely his services to those who could not pay without hardship.

He has left two worn and time-stained books[1] of three hundred and sixty manuscript pages, and ample evidence of "Liber No. 3." In these are entries from 1773 to 1790, not always chronological in arrangement, and very likely not complete for the time they include, but presenting an interesting picture of Dr. White's practice. They are written in a hand like copper-plate, and contain the record of the rides or walks the doctor took, of the drugs he exhibited, the teeth he pulled, the bloodletting he did, and of the sums he charged and collected years after, or often not at all.

The visit and each item of treatment are entered separately. For instance, after a series of visits and doses to Abial Chamberlain, who seems to have been sickly, occurs the entry:

"Sept. 10th 1784. To visit 2/ Physic 1/ Emet 1/ Bleeding 1/ Sal Nitre 1/—6."

The least charge for a visit is one shilling, and the greatest—to Upper Coos—is sixty shillings. While commonly each place had its own uniform rate for a visit, occasional great variations are noticeable, for reasons which do not appear; but the weather, the difficulty of travel, the urgency of the call, and the poverty of the patient may have been factors, as well as the custom of clubbing together of several families to pay for the doctor's visit. The variations occur frequently in the same account: To Corinth charges were all the way from one to twenty shillings; to Haverhill, two to six shillings; to Apthorpe, two, three, and twenty-seven shillings; and in Newbury, his home, one to four shillings. Medicine was usually one shilling for each potion, occasionally two shillings; bleeding was always one shilling; tooth-pulling, one shilling; dressing a wound, one shilling; lancing a sore, one shilling; setting an arm or leg, six shillings; "Attendance on your wife's Travel" was twelve shillings.

These two books show accounts of about two thousand five hundred pounds, many of which have no credit side; many of the larger accounts ran six and eight years, and then were settled by notes of hand; and, indeed, this mode of settlement seemed applicable to accounts long or short, large or small. In one case the doctor took a yoke of steers to balance an account of £5, and a watch, at another time, to close up a £6 account. From an entry of seven dollars as £2 2s., it appears that the dollar was equal to six of the twenty shillings that make a pound, or a shilling was the present New England shilling of 16⅔ cents.

In his materia medica the good doctor had a wide range. One hundred and fifty-two remedies are noted in his books. Of this number thirty-six are used but once, ten twice, and eleven three times. It was his satisfying custom to give medicine; and among the simple folk of his remote time and place, doubtless discontent would have prevailed, and the accounts would have run on for two or three years longer if, when the doctor came, nothing happened. But no charge of neglect can be based upon his records; of 4,271 visits, only 181 were unadorned by the exhibition of some drug. As he has left account of 8,471 doses, or operations, in his 4,271 visits, and as 1,630 of the doses were physic, the patients must have had every reason to be satisfied. The physic, which appears once in every five administrations of medicine, was no doubt a liver-coercing, peristalsis-stimulating mixture of potent drugs, kept in a well-known jar, from which it could, in his absence, be doled out to the regular customers by some member of his household. Next to physic he relied upon camphor, to the extent of 994 doses. Then followed 650 doses of valerian, 444 of cream tartar, 288 of balsam or cortex of Peru, 275 of myrrh, 262 of tartar emetic, 258 of rhubarb, 244 of "bitters." He gave 228 "vomits," 148 doses of antimony (crude or wine), 137 of lavender, 136 saline draughts, 116 doses of "contraery," 93 of calomel, 83 of assafœtida, and 81 of chamomile. He used, during the period of his books, guiacum, jalap, magnesia, castor, silla and sapo pills more than fifty times each; and paregoric, liquor laudani, cascarilla, gum arabic, oil of amber, elixir vitriol, elixir salutis, annis seed, gum ammoniacum, aloes, cinnamon, licorice, pectoral balsam, and sweet spirits of nitre twenty or more times each. Among his remedies were pill cochiæ, pill rufi, pill æthiops, pill cathartic, sapo pills, female pills, mercurial pills; Hooper's, Anderson's, and Locker's pills; elixirs vitriol astma, solutis, proprieta, stomatica. Less familiar than most of these are the names, as they occur in his books, of sago permeum, sp. sal c.c., ens veneris, Roman vitriol, flos bolostinos, lac ammoniac., mellilot, cinnabar, sal tartar, "contraery," sal mirabile, oculi cran-

[1] These books were examined through the kindness of Hon. A. S. Batchellor, of Littleton, N. H.

corum, spirit hierapic., flos benjamin, crocus, pickleura, calibietes, vorsena, sal cor cerebrini, winter bark, hat case. British oil, Bateman's drops, Thurlington's drops, and Hooper's pills display their ancient labels and credentials to-day.

The doctor practised venesection, it would seem, without excess. Five hundred and four bleedings he puts down, at one shilling each—about a hogshead full of blood. He attended to it, to some extent periodically, and often there occurs a series of entries of the same date; and many times appears "To bleeding two," and occasionally "To bleeding three." In the account of Mr. Thomas Homer, of Mooretown, are these entries:

April 25, 1785. Bleeding two.
May 4, 1785. Bleeding.
May 9, 1785. Bleeding.
June 9, 1785. Bleeding.
July 3, 1785. Bleeding.

A few mild doses were interspersed, and recovery perhaps took place, as pulling a tooth was charged on November 26th of the same year.

Dr. White's biographer, in the journal cited, attributes to him great skill and repute as a surgeon, but these records of his earlier practice give little indication of extended surgical work. They note the pulling of seventy-six teeth, the dressing of fifty-seven wounds, the setting of ten arms, three legs, and one "bone," and mention only seven cases of confinement. They do, however, give striking glimpses of the vigorous courses of treatment which our sturdy ancestors could undergo before either disease or patient succumbed.

Major Jothan Hayward, for instance, upon May 29, 1784, had "vomit, physic, bleeding."

Moses Moore seems to have furnished a difficult case. His treatment was: On

November 4th. Physic, calomel.
November 10th. Physic, two portions.
November 11th. Physic.
November 12th. Physic, two portions.
November 15th. Physic.
November 16th. Two dozen sapo pills.

Mrs. Colonel Robert Johnston, it appears, was confined upon October 13, 1787. For six days all went well; at any rate, neither visit nor medicine is recorded, until the exhibition, upon October 19th, of physic, saline draught, followed and continued,

October 20th, by Physic.
October 21st. Physic.
October 22d. Physic, two blister plasters.
October 23d. Physic.
October 24th. Two portions, physic.
October 25th. Camphor.
October 26th. Valerian.
October 27th. Physic.
October 28th. Physic.

The treatment ceases until November 16th, then physic.

November 17th. Physic.
November 20th. Emetic.
November 21st. Physic.
November 22d. Valerian,

and, unfortunately, now the record runs over into missing "Liber No. 3."

Abial Chamberlain had a severe illness, which began April 23d and terminated May 14, 1784. The internal evidence, the increasing frequency and sudden cessation of the visits, and the opening of an account later with the Widow Chamberlain, would lead to the conclusion that Mr. Chamberlain's illness at this time terminated in death, were it not that some five months later the physic, emetic, bleeding, and nitre were administered to one Abial Chamberlain. So, without historical information, not at hand, the result remains matter for speculation. During this period of twenty-two days Mr. Chamberlain was bled three times, took four emetics, and had two blister plasters applied; took six doses of cream of tartar, five of physic, five of wine of antimony, four of tartar emetic, two of British oil, two of camphor, one of calomel, one of Bateman's drops, and one of Thurlington's drops. The last medicine given, upon May 14th, was tartar emetic, and the visits ceased.

The good doctor's useful career continued many years, and upon February 26, 1847, he died, at the ripe age of ninety-seven.

EDWIN J. BARTLETT, M.D.
HANOVER, N. H.

ROUGH-AND-READY COUNTRY EXPERIENCES.

To the Editor of The Medical Record.

SIR: I have read the experiences of several country doctors of late in THE RECORD. I would not wish to reproach my city brethren with a lack of the rough-and-tumble experience of a country doctor. I am inclined to congratulate him, rather, on his more fortunate choice in locating where tall towers cast their shadows instead of sylvan shades. We beguile many lonely hours, astride of the lagging-footed saddle-horse, with THE RECORD, our only companion—its advertising leaves in tatters, used to put up powders where even an old newspaper is not procurable.

When I entered practice it was in the hills of West Virginia. Was called with another physician to amputate an arm, patient living nine miles away. It turned out neither of us had more instruments than a small curved bistoury and a scalpel, with some needles and silk. Not to be balked (as we were much in need of the fee), we borrowed a pocket-knife of a friendly machinist, wrapped the handle with newspaper, and went on rejoicing. My friend administered an anæsthetic while I amputated, three inches below the elbow, an arm as large as an ordinary man's calf. We now discovered that we had forgotten to bring a bone-saw, which discovery had been prearranged. Called for and got a rusty hand-saw, which rattled over the bones until the sweat poured down from the face of the operator like rain. Patient made a rapid recovery, which fact alone saved us from the wrath of "regulators," who threatened us, should our patient die, with a hemp cord.

While living in a Colorado mountain-town I started, at 4 P.M., one November day, through a foot of snow, with thermometer 10° below zero. Rode forty miles on horseback, crossing the range, which was fast blocking up with snow. Reached patient at 2 A.M., too benumbed to get off my horse. Exhaustion brought on copious watery stools. Braced up on a glass of brandy and reduced dislocated shoulder. The three following days made round-about trip of one hundred and sixty miles, crossing range again. Reached home and was sick a week. Physicians who had been in the mountains years refused to go; but I was a green mountaineer, and did not know the dangers of such a trip until afterward, and the largest fee of my life was irresistible—just $100.

Here in the Southern Ohio hills I was last fall called in haste six miles. I was caught on the road in my buggy with my four-year-old boy. Hurried on for four miles through mud and cold rain. Took harness off and climbed onto my wet horse, bareback (leaving my child at a farm-house), and rode and swam up a creek-flooded road for two miles—saw the complacent face of an aged lady who "had had a pain in her side."

Rode and swam back to buggy and drove through cold wind, wet and chilled through, until near home, after dark; got stuck in a mud-hole; broke single-tree; horse ran away; dropped boy in mud-hole, head up; and ran horse into a bank. Respectfully,

L. HOWE, M.D.
WELLSTON, O.

A GERMAN MEDICAL SOCIETY has recently been organized in Philadelphia. Dr. F. H. Gross, of the German Hospital in that city, was the first chairman of the society.

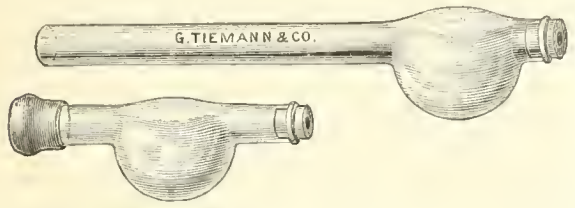
New Instruments.

A NEW ARTIFICIAL LEECH.[1]

By HENRY FLOOD, M.D.,

ELMIRA, N. Y.

I HAVE for some years been in the habit of using the leech in the treatment of many diseases, and have had considerable trouble in obtaining any which were sufficiently active. For nearly a year I have endeavored to overcome the difficulty by using artificial leeches. I first tried a glass tube, closed at one end, from which the air had been expelled by the vapor of ether, but I found that the ether hastened the coagulation of the blood and impeded its flow. There was also no way of regulating the suction-force, which would be either so light that it would not



draw blood, or so strong that it would cause pain and often injure inflamed tissues. I then used an instrument made after the plan of Heurteloup's artificial leech, which also on trial was found to be very unsatisfactory. Finally, I adopted the plan of using a glass tube attached to an aspirator. With an aspirator a suction-force sufficient to draw blood can be produced, and the instrument may then be stopped before the pressure of the tube on the tissues becomes painful. I found that a glass tube from one-half to three-quarters of an inch in diameter, attached to an aspirator, worked very well, and could be applied to almost any surface. The objection, however, was that the calibre of the aspirator tube was so small that it became easily stopped with coagulated blood, and another objection was that considerable time and patience were required to remove the dried and coagulated blood from the aspirator. I have made some leech tubes, shown in the accompanying illustration, which, after an experience with them of several months, have given satisfaction in every detail. This leech consists of a glass tube with a bulb of a capacity of one fluid ounce. The mouth of the tube is made broad enough to prevent constriction of the tissues, and is covered with a rubber band, when necessary, in order to protect the inflamed tissues from injury by the hard surface of the glass. Two sizes are made; one with a short neck, for use on external surfaces, and the other with a long neck, to be applied to the uterus, tonsils, or other surfaces in the interior of cavities. The distal end is constructed so as to fit the screw on the end of the aspirator tube. The advantages of this instrument are that it can be attached to any form of aspirator, and that the blood will soil only the leech tube, which can be readily cleaned. The opening in the tissues can be made by one or two incisions with a sharp-pointed lance, or with one of the circular scarifying instruments which are in the market. The only times that I have not drawn a satisfactory amount of blood were when the incisions were too superficial. This instrument makes artificial leeching very simple. It is cheaper than the natural leech, always ready for use, and is always sure to withdraw blood in a satisfactory manner, and in sufficient amount.

THE ROYAL COLLEGE OF PHYSICIANS OF LONDON has received a legacy, by the will of the late Dr. Gavin Milroy, of £2,000 for the endowment of a lectureship on public health and sanitation.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 6 to March 12, 1887.

ALDEN, C. H., Major and Surgeon. Ordered for duty at United States Military Academy, West Point, N. Y., August 28, 1887, relieving Lieutenant-Colonel Andrew K. Smith, Surgeon, who will then report by letter to the Surgeon-General. S. O. 52, A. G. O., March 5, 1887.

CARTER, WILLIAM F., Captain and Assistant Surgeon. Granted leave of absence for one month on Surgeon's Certificate of Disability. S. O. 25, Department of Texas, February 24, 1887.

MCCREERY, GEORGE, Captain and Assistant Surgeon. Leave of absence extended one month. S. O. 52, A. G. O., March 5, 1887.

JOHNSON, R. W., Captain and Assistant Surgeon. Ordered for temporary duty at United States Military Academy, West Point, N. Y. S. O. 51, A. G. O., March 4, 1887.

EDIE, GUY L., First Lieutenant and Assistant Surgeon. Granted leave of absence for one month, to take effect about March 1, 1887. S. O. 27, Department of Texas, February 28, 1887.

Official List of Changes in the Medical Corps of the United States Navy for the week ending March 12, 1887.

BRADLEY, GEORGE P., Surgeon. Detached from Naval Hospital, Philadelphia, Pa., and granted six months' leave.

STEELE, JOHN W., Passed Assistant Surgeon. Ordered to Naval Hospital, Philadelphia, Pa., without delay.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 12, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	5	4
Scarlet fever	44	11
Cerebro-spinal meningitis	4	4
Measles	177	29
Diphtheria	108	57
Small-pox	14	1
Yellow fever	0	0

POSSIBLE DANGER FROM PEPSIN.—It is suggested by Dr. Wood (*Therapeutic Gazette*) that in ulcerated conditions of the bowels or stomach pepsin may enter the blood and cause septicæmia. Dr. E. Chenery reports a case which he thinks confirms this view.

PHOSPHORUS IN INTERMITTENT FEVER.—Dr. Soshinski recommends phosphorus very highly in intermittent fever. He gives five drops of the oil of phosphorus, well diluted, three times a day. He states that he has been in the habit of prescribing it for all his cases during the past five years, and has had excellent results from its use.

AGAINST PASTEUR.—Up to November 1, 1886, France gives the following hydrophobia statistics for the year: Persons dying from hydrophobia *assisted* by Pastorian treatment, 14; persons dying without the assistance of Pastorian treatment, 17; total, 31. The annual average of such deaths in France has heretofore been 27.—*Science Libre.*

Wet-Nursing in Paris.—The following quotation from a Parisian correspondence appears in *Gaillard's Medical Journal*, and will be read with interest in view of the attention recently given to the subject in our city: "These peasant matrons have been spoiled by the upper classes, where they are indulged to an extent that defies description. They are decked out as for a feast; they rule the household, in return for which they give what the mother is apparently unwilling or unable to give, and what old-fashioned folks still persist in considering the sweetest joys of maternity. Thackeray made Becky Sharp French by the mother's side. It proved his acumen; had he done otherwise, English readers would have been inclined to tax him with exaggeration in depicting his heroine as utterly indifferent—nay, sick and tired—of her pretty son because he interfered with her enjoyment of society. In Paris, however—and in the large provincial centres, whose chief delight it seems to ape Paris—the Becky Sharps are in a majority. The statistics of last year's births for the city of Paris amount to 62,000. Out of these, 17,000 were despatched to the country. I may safely defy anyone curious in these matters to take a six hours' stroll through one or two of the best or second-best quarters of Paris, and to find more than one well-dressed mother out of every thirty unflanked by a wet-nurse. He can easily try the experiment for himself, seeing that there is a difference in the costume of the mere nurse-maid and the wet-nurse. The latter is got up very theatrically and prettily, with a wreath of beautiful ribbons round her exquisitely embroidered cap, two long streamers of the same ribbon floating in the wind, a handsome dress and ample cloak, often lined with silk, and a lace apron. She is part of the show of a fashionable entertainment in Paris. If my observer has done this, if he calculates the 17,000 infants gone to the provinces, and jots down a computation based upon the fraction of the remaining 45,000, he will arrive at the conclusion that probably about one of every ten mothers nurses her own baby."

A Solution of Salicylate and Iron used for Rheumatism in New York Hospital is made as follows:

℞.	Acid. salicylic	℥j.
	Ferri pyrophosphat	gr. v.
	Sodii phosphat	gr. j.
	Aquæ	℥ ss.

M. Sig.—One drachm every two hours.

A Plethora of Doctors.—It would appear that this country is not alone in the overcrowding of the medical profession. Spain is suffering from the same cause, and a young physician's prospects there are about as uncertain as they are here. They seem to be wiser there, however, as it is stated that the number of medical students is decreasing at a very rapid rate, only twenty men having matriculated in the medical department of the University of Madrid in the fall of 1886.

Duhring's Treatise on Diseases of the Skin has been translated into Russian. French and Italian translations of the same work were made some time ago.

A Practical Surgical Hint.—Dr. John F. Lockwood, of Batavia, Ill., writes that a young man came into his office having severed the radial artery in the wrist. His brother, who accompanied him, controlled the hemorrhage from the proximal end by means of pressure while the writer occupied himself with the distal end, and endeavored to seize the bleeding points. He was unable to find these readily because of the constant oozing of blood which obscured the field of operation, and sponging was of little avail. It then occurred to him to blow away the blood, which he did, and found that by this means he could keep the wound so free that the ends of the arteries were readily found and tied. He says that with a little care there need be no spattering of blood, but that a well-directed stream of air simply clears it all away from the wound.

Treatment of Erysipelas.—For the treatment of erysipelas Dr. Archangelski has tried a number of applications, and finds that their comparative efficiency is represented by arranging them in the following order: (1) benzoic acid; (2) tincture of iodine and turpentine, as ointment; (3) sulphate of copper; (4) sulphate of iron; (5) oxide of zinc; (6) naphthalin; (7) solution of perchloride of mercury, 1 to 300; (8) chloride of zinc; (9) iodoform.

Bicarbonate of Soda in Tonsillitis.—The treatment of tonsillitis by frequent local applications of carbonate of soda, which has been practised and recommended by Dr. D. Juan Giné, has been put to a series of tests by another Spanish physician, Dr. D. Rovira y Oliver, who deduces from them the opinion that, though it is often beneficial in cases where the parenchyma of the tonsil is affected, it is of much less value than many other applications in cases which are merely superficial and catarrhal.

A Good Dentifrice.—Precipitated chalk forms the best basis for a tooth-powder, to the base of which may be added pulv. saponis and ol. eucalypt., a drachm of each; and, if there is no objection to the taste, half a drachm of carbolic acid.—*The Lancet.*

Measure of a Man.—Broca formulates the rule that the body should weigh as many kilogrammes as it measures in centimetres, after deduction of the first metre, *e.g.*, a man who measures one metre, eighty centimetres —180 ctm.—should weigh eighty kilos. If he weigh more or less, he is too stout or thin. As man increases in years he decreases in weight, and there is a compensating decrease in height.

Curious Action of Remedies at a Distance.—M. Jules Voisin has made two highly interesting experiments, at the Salpêtrière Hospital, on hysterical patients on whom he studied the action of telepathic remedies (*médicaments à distance*), such as metals and the magnet. He explained the phenomenon of various changes of personality presented by one of his patients, M. V——, the same individual who was experimented on by MM. Bourru and Butot (see Congress of Grenoble, 1885, and Société de Biologie, 1885). M. Voisin's experiments were made with corked and sealed phials of an opaque color. He was himself ignorant of the contents of these phials, and was careful not to utter a word in the patient's presence. He threw the subject into a lethargic, somnolent, and cataleptic state, but obtained no result under these conditions. When M. Voisin made his experiments on any patient in a waking state, the latter immediately fell into a hypnotic state, and exhibited symptoms of disturbance —nausea and vomiting. If the name of a drug, of which the effects are well known, or the effects of any medicament whatsoever were mentioned, during the state of hypnotism, the patient immediately manifested the physiological effects of these remedies. Suggestion and unconscious suggestion were thus manifested. In another series of experiments M. Jules Voisin observed, during one of the three phases of somnolence (lethargy, somnambulism, catalepsy), the state of one of his subjects, V——; he was not affected by the magnet. In the waking state no effect took place unless the magnet was seen by the patient, when it induced an attack, probably through suggestion. Gold and mercury caused redness and blisters if V—— was aware of their presence; these results were obtained likewise during somnambulism. By suggestion, the effect of metals was destroyed or produced without their presence, and if the contact of metal took place without the knowledge of V——, when he was awake, no effect occurred. General sensibility, sensory and motor sensibility, and the psychical state were affected by suggestion. M. Jules Voisin therefore believes it possible that the phenomenon of change of personality, as described by MM. Bourru and Butot, represents the last stage of an hysterical attack.—*British Medical Journal.*

ON BACTERIA IN ICE, AND THEIR RELATIONS TO DISEASE, WITH SPECIAL REFERENCE TO THE ICE-SUPPLY OF NEW YORK CITY.

AN EXPERIMENTAL STUDY FROM THE LABORATORY OF THE ALUMNI ASSOCIATION OF THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

BY T. MITCHELL PRUDDEN, M.D.,

DIRECTOR OF THE LABORATORY.

OUR knowledge of the dangers of impure water has become much more precise since we have learned that many common and fatal diseases are caused by tiny vegetable organisms, called bacteria, which such water may contain. As the questions relating to a pure ice-supply are for the most part identical with those relating to the water-supply, in so far as ice is used for drinking purposes, it seems necessary to look for a moment, before passing to the immediate subject of this investigation, at the new methods of water-analysis and the practical advance which their application has brought about.

It was formerly the practice, whenever the fitness of a water-supply for drinking and culinary purposes was called in question, to subject the water, when this was feasible, to a careful chemical examination, and a vast amount of learning and technical skill has been expended in arriving at accurate methods of analysis. But the great difficulty with the simple chemical analysis of water has always been to know exactly what significance to attach to its results. The presence of a considerable amount of organic matter in water, particularly if this could be shown to be of animal origin, has been regarded as a sufficient evidence of its unfitness for drinking purposes. Not because organic matter is in itself unwholesome, but because in the forms of water-contamination it usually signifies decay, putrefaction, or the presence of animal excretion.

More recently, since certain diseases as well as all putrefactions have been shown to be caused by bacteria, the presence of organic matter in drinking-water has been looked upon as indicative of the presence or of the action of these organisms, and in this way furnishes a criterion of the probable salubrity of the water. But chemical examination can determine only inferentially the presence of bacteria. The new methods of research, however, by which it has been shown that certain diseases, such as consumption, typhoid fever, and cholera, are caused by the presence and action in the body of certain species of bacteria, are directly applicable to the analysis of water. Thus it is no longer necessary to *infer* the presence of bacteria in a given sample of drinking-water from its organic contents, but the bacteria may be actually seen, counted, and their species and actions on the animal body definitely determined. The new method of water-analysis, by which its living bacterial contaminations are determined and studied, is called the *biological analysis.*

It should not be inferred that the biological has superseded the chemical method of water-analysis, but, so far as we can at present judge, it forms a very important addition to it. Indeed, it may be said that, so far as our knowledge of a certain class of bacterial diseases, such as typhoid fever and cholera, is concerned, the biological analysis is the more important; but that this is true in all cases it would certainly be premature to say. For it is already known that in some cases the results of chemical and biological analysis do not coincide. A chemical analysis may, for example, show so large a degree of organic contamination as to render utterly unfit for potable purposes water which at the moment contains comparatively few bacteria. So that it would seem that, in many cases at least, the two methods, mutally supplementary, should go hand in hand.

There are, of course, many cases in which a careful scientific analysis of water is entirely superfluous. When the water is bad-smelling, or when it is obvious that it is mixed with animal excreta, even though it should look clear and colorless, an ordinary common-sense of decency and cleanliness, to say nothing of the danger of incurring disease, should lead to its avoidance for drinking purposes, without some efficient purification. This seems obvious enough; and yet a very little attention to the matter will reveal to the observer instances, sometimes on a large scale, of almost incredible filthiness and foolhardiness in the use of evidently impure water by families and communities which fancy that they are civilized.

A direct microscopical examination of water for the presence of bacteria is impracticable, first. because the individual organisms are so exceedingly minute that it would be almost impossible to examine completely any considerable quantity of water; and, second, because in this way, even if the bacteria could be all seen and counted, we should be unable to determine which of them were living, and as it is only living bacteria which are capable of inducing disease it is these alone which are of sanitary importance.

The new methods of biological analysis of water are very simple in principle, but require for their execution considerable patience, care, and experience.

The biological method is briefly as follows: In the first place, all the vessels and instruments which will come in contact with our water and the food which we prepare for the nourishment of the bacteria are completely freed from all living germs, which are almost omnipresent in the air and on the things we touch. This is usually done by prolonged heating or steaming. Thus freed from all living things, no matter how small, our materials are said to be *sterilized.* The food which we prepare for the bacteria in water-analysis is usually beef-tea, with a little pepton and common salt and enough gelatin to make it moderately solid when cold. This is called the nutrient gelatin, or culture-medium, and it is poured into glass test-tubes, a few teaspoonfuls in each.

In this medium most of the bacteria which are commonly found in water will readily grow. It is clear and transparent and usually slightly yellowish in color.

Now, one of the prominent characteristics of these lowly organisms, the bacteria, is their capacity, under favorable conditions of nutriment and temperature, of rapid and enormous increase in numbers. This occurs by the slight enlargement of the individual bacteria and their division across the middle into two. These two then each again divide, and so on until within a short time an almost innumerable number of new individuals are produced from the original germ, each one the exact counterpart of its ancestors. It is estimated that, if the conditions are favorable, a single bacterium by this process of growth and subdivision may give rise to more than six-

teen and a half millions of similar organisms within twenty-four hours. But so minute are most of these that at an average estimate the whole of these sixteen and a half millions would occupy a space less than the sixteen-hundredth of a cubic inch.

When a water-analysis is to be made, the nutrient gelatin in one of the tubes is melted by gentle heat, and thoroughly mixed by shaking with a measured quantity of the water to be examined. In this way the bacteria contained in the water, always an unknown quantity and of course quite invisible, are evenly distributed through the gelatin. To insure accuracy, duplicate analyses are always made. The quantity of water used is usually one cubic centimetre, and this is taken as the standard quantity in which the bacterial content is expressed.

It should be remembered, in studying the results of the analyses which are to follow, that one cubic centimetre (1 c.c.) of water is a little less than one-third of a teaspoonful.

The portion of gelatin mixed with the measured quantity of water is now poured out onto a sterilized glass plate, and is spread upon it in a thin, even layer. The plate while this is being done rests upon a level surface kept cool by ice, so that the gelatin soon solidifies. The plate with its gelatin-layer is now put into a clean glass saucer, covered so as to be free from dust, and set away in a moderately warm place.

Now, the single bacteria which are evenly distributed through the gelatin commence to grow, but as they are each inclosed by a solid wall of the nutrient gelatin they grow in a little heap or mass, which is called a "colony." In the course of from two to four days these colonies, each now containing thousands of individual bacteria, have become large enough to be readily visible to the naked eye, or with the aid of a low-power magnifying-glass. We have now only to count these colonies and we know exactly how many living bacteria were present in the one cubic centimetre of water used for analysis, because each visible colony is the result of the growth on the spot of a single invisible bacterium which was caught here by the solidifying gelatin. Of course, if two or more bacteria chance to have clung together when the water was mixed with the nutrient gelatin, our estimate of the number of original germs will be too low, but if the mixture was carefully made this so seldom occurs that the experimental error is slight.

To facilitate the counting of the colonies, a glass plate ruled off into equal squares is usually placed over the gelatin-film, so as not to touch it; and thus, if we do not count all the colonies, we can count those found under several of the squares, and then, by multiplying the average number under the squares which are counted by the whole number of squares, we find the number of colonies, which is the same as the number of living bacteria in the volume of water analyzed.

If we wish to study these bacteria further, which is sometimes of the utmost importance, so as to identify their species, study their effects on animals, and find out whether or not they are disease-producing or pathogenic, we put the glass plate under the microscope, and with a fine, sterilized platinum wire set in a glass handle we take out a minute portion from one of the colonies and put it into a fresh tube of nutrient gelatin, where it will grow until a sufficient quantity of the material is produced for experimentation. Thus, no matter how many different species of bacteria were growing side by side on the gelatin-plate, we can take out under the microscope a little of each by itself and transfer to separate tubes, and thus get what are called "pure cultures" of all the separate species.

It is always a matter of surprise to one unaccustomed to such an exceedingly delicate mode of water-testing to find what large and varying numbers of these living organisms ordinary water may contain. We usually congratulate ourselves that in New York we have an especially excellent and pure water-supply, and this is in a certain sense true. But a series of thirty-two analyses of the Croton water, as it is delivered through one of the faucets at the College of Physicians and Surgeons on different days during October, November, and December, 1886, and January and February, 1887, shows the lowest number of living bacteria to be 57 to the cubic centimetre; the highest, 1,950; while the average in the thirty-two analyses is 243.

Now, when the first accurate biological analyses of water were made, and the very large numbers of living bacteria which it often contains were noted, it was thought, since certain diseases, and particularly typhoid fever, had been frequently shown to be associated with bad and sewage-contaminated drinking-water; and, furthermore, as typhoid fever and several other diseases were known to be caused by bacteria, that any water which was proved to contain a considerable number of living bacteria was unfit for drinking purposes.

But as our knowledge on this subject has gone on increasing, we have learned that this view must be very materially modified. Bacteria are almost everywhere present, sometimes in enormous numbers, in soil, air, and in parts of the human and animal body which are directly or indirectly in communication with the air or with foods introduced from without. By far the larger proportion of bacteria are, so far as we know, perfectly harmless. Their rôle in nature is to tear down organized bodies into their simpler constituents, a small part of these being used for their own nutrition and growth while the larger part is given up to other organisms for their life purposes. The bacteria are thus indispensable and omnipresent factors in the working out of the organic processes of nature. It still remains true, however, that a certain number of species, which can live in water as well as elsewhere, can and do produce deadly diseases, and are responsible for some of the most frightful epidemics.

Recent researches[1] have shown that there are certain species of bacteria which find in water of the purest kind, even in distilled water, when once they get a footing there, most favorable conditions for their growth and proliferation, so that it is always necessary to make an analysis of water immediately after its collection, lest we should get as the result of analysis, not the number of bacteria originally in the water, but this number plus those which have grown since it was taken from its source.

Thus Cramer,[2] in Zurich, found that the bacteria in the city water increased in number two thousand seven hundred times in a few days. Leone[3] found that Munich water, containing, when freshly drawn, only five living bacteria per cubic centimetre, after standing for five days held more than half a million. This fact has been confirmed by numerous observers.

These bacteria, which can proliferate in water to an almost incredible extent, and which may be called, *par excellence*, "water-bacteria," are not, so far as is at present known, capable of producing disease in man; but, on the other hand, they have not for the most part been sufficiently studied, so that we can safely assume that they are harmless if taken into the body in large numbers.

Furthermore, some of the bacteria which are known to be the cause of disease in man can grow and increase in number in water, and particularly, as Frankland[4] has shown, in sewer-water, which contains a considerable quantity of organic material which may serve as food.

It is of great importance to know whether the source from which the water to be examined is taken is stagnant, or whether water is running away from it and a fresh supply is flowing in or filtering in through the soil. This is particularly important in wells and lakes; for it is found that a well which has been undisturbed for a time may contain a vastly greater number of bacteria than after a vigorous pumping from it. In a flowing stream, to which a large quantity of pure fresh

water is constantly being supplied, this increase of water-bacteria from stagnation is not so important a factor.

Thus it will be seen that the biological analysis of water, important and precise as it is, and apparently leading us directly to the source of many outbreaks of infectious disease, is, after all, beset with many difficulties as soon as we come to the exact interpretation of its results.

At present, the simple statement that a given sample of water contains a large number of living bacteria affords little more just ground for its absolute condemnation than we should have for saying that all flowering plants are unfit for food because a certain number of them are powerful poisons. When we have before us the numerical results of the biological examination of a given water, the real problem still lies in determining what significance should be attached to them. To solve this we must carefully weigh all the general considerations and facts set forth above. We must find out whether a considerable proportion of the bacteria in the sample are or are not the, at least relatively, harmless water-bacteria which may have grown there; whether the water has been stagnant, or other conditions have existed favoring their increase. We must, above all, find out, if possible, whether there has been a chance for the pollution of the water with sewage or excrementitious matter of any kind. If this be the case, and large numbers of bacteria, not the relatively harmless water-bacteria, be present, we may justly infer that the natural processes of water-purification have not been acting or efficacious, but that the conditions have been favorable for the prolonged existence of the sewage-bacteria, and, among these, of disease-producing forms.

A great variety in the species of bacteria present in a water is rather indicative of sewage-contamination.

Finally, bearing in mind that even very pure spring-, river-, lake-, and well-water may, and frequently does, contain considerable numbers of bacteria, and also that our present knowledge of the disease-producing powers or harmlessness of these ordinary bacteria when taken in large quantities is still very meagre, it seems safe to say in general, for the sake of having some sort of temporary standard until increased knowledge shall give us a more exact one, that any water which contains more than fifty to one hundred living bacteria to the cubic centimetre should not be used without some kind of purification, such as boiling, filtering, etc.

Of course, this number is fixed upon somewhat arbitrarily, and with the sole intention of indicating in a general way what from a bacteriological standpoint may be regarded as a safe rule. Fraenkel, who writes with the approval of Dr. Koch, assumes that good drinking-water should not contain, at most, more than fifty living bacteria to the cubic centimetre. It should always be remembered that absolutely pure water contains no bacteria at all; that which has just been said applies only to apparently pure water. If water is known to be either immediately or remotely polluted with sewage or human or animal excreta, it should under no circumstances be used for drinking purposes without filtration, or some other efficient form of purification, whatever the number of bacteria which it may contain. In any case in which sewage-contamination could be positively excluded from the position and surroundings of the source of the water, so far as our present knowledge goes, the limit of safety might be placed considerably higher.

It is very well known that, by a suitable system of filtration, water which contains so large a number of bacteria as to be entirely unfit for potable purposes may be rendered entirely wholesome; and one of the great practical advantages of the biological and chemical analysis of water consists, not only in the power which it gives us to determine whether or not a given water is fit for use, but also, if filtration is called for, we are thereby enabled to determine positively whether or not the chosen method and practice of filtration is really efficacious.

The so-called spontaneous purification of water by sedimentation or exposure to air will be considered below in so far as it concerns our present theme.

All of the above data concerning bacterial water-contaminations and water-analyses apply equally to the problems which ice-impurities present, to which we now turn.

The biological analysis of ice is conducted in precisely the same way as the biological analysis of water, except that the piece of ice to be examined must first be carefully cleansed and then melted. The details of the ice-analyses made by the writer, are as follows: A number of small glass beakers, one for each specimen of ice, were carefully sterilized by heat. A piece of ice about one inch in cube was cracked from the sample lump, and put into one of the sterilized beakers, where it was repeatedly rinsed with boiled distilled water, which by analysis was found to contain no living bacteria. The last rinsing-water was finally drained off, and the beaker set into a hot-water bath until a small portion of the ice was melted; the remaining ice was rinsed with this melted portion, which was then poured off. This operation of rinsing in its own meltings was repeated. It may be safely assumed that in this way the remaining small fragment of ice was entirely freed from any external contamination. Now enough of this for analysis was allowed to melt, and immediately a measured quantity of the water, either one cubic centimetre or one-half this quantity, was mixed with the nutrient gelatin and plate-cultures were made as described above. Duplicate analyses of either of the above quantities were made for the purpose of control; the smaller quantity was used only when there was reason to suspect that the ice contained many bacteria, as in this case the counting of colonies in a larger dilution is more readily and accurately done. In every case the water from the melted ice was used within five minutes of its melting, so as to preclude the possibility of an increase in the number of bacteria, as mentioned above.

It should be stated here that samples of ice which contained evident gross impurities, such as grass, straw, particles of sand, leaves, etc., were in all cases rejected as not fairly representative for analysis. Such ice is ordinarily carefully excluded from the harvest by the more responsible companies, but sometimes, particularly when the crop is short, as was the case during the last winter, does not infrequently find its way to the doors of consumers.

It is a popular belief that water in freezing purifies itself, so that water which would be unpalatable and seem unfit for drinking purposes may be regarded as quite pure when frozen. This belief is to a certain extent true, or, rather, rests upon a basis of truth; for, as is well known, coarser foreign particles may be to a certain extent thrown out in the act of freezing, and the same is true in more marked degree of certain inorganic salts, coloring materials, etc., held in solution. The beautiful clearness and sparkle of well-formed ice tends to confirm the belief that the act of freezing is a very perfect purifying agency. It has, however, been shown that, so far as organic matter in solution is concerned, freezing by no means entirely purifies the water.

As is well known, the vitality of quite highly organized beings, such as toads, frogs, worms, etc., is said to be not infrequently retained during a prolonged enclosure in ice, and stories of a more or less sensational nature concerning the discovery of such beings in ice are common enough in the newspapers. But these are exceptional cases, interesting only as facts in biology, and have no practical bearing whatever upon the purity of ice in general.

In regard to the bacteria, it should be remembered that they are so exceeding minute that they may exist in water in enormous numbers without in the slightest degree impairing its clearness and transparency. Thus a series of experiments on the typhoid-fever bacteria by

the writer showed that more than one and a half million of these organisms may be diffused through a tablespoonful of perfectly clear distilled water without in the least appreciable degree impairing its transparency as it is held to the light in a thin-walled glass tube half an inch in diameter. By passing a beam of light from a lens through the tube the faintest opalescence was detected.

The literature on the subject of the effect of cold on bacteria is not extensive, especially by the use of the modern methods. These enable us not only to tell whether or not all of the bacteria exposed to cold are destroyed—which was about all the older methods could do [5]—but they enable us to tell just how many are killed by a given exposure, and what species are most vulnerable, either in a mixture or in pure cultures.

It was shown by Cohn,[6] more than a decade ago, that certain bacteria were capable of retaining their vitality after an exposure of several hours to a very low temperature, in one case to 0° F., and similar observations have been repeatedly made.

Pengra,[7] in 1884, apparently by the method of simple microscopical examination, concluded that as regards bacteria in water there may be a purification of about ninety per cent., but his method of working would suggest the possibility that a part, at least, of this purification might, in his experiments, be due to the simple sedimentation of the bacteria before or during the freezing.

In a recent report to the State Board of Health of New York, on the purity of ice from several sources, by James T. Gardiner,[8] experiments made by Hailes at his request showed that ice may contain considerable numbers of living bacteria. This general observation has been repeatedly made.

The first complete and accurate series of biological analyses of ice were made in Berlin, Germany, less than a year ago, by Fraenkel.[9] His experiments show that while the number of living bacteria contained in a given sample of water is often greatly reduced by freezing, sometimes as much as ninety per cent. in three or four days, yet that the resulting ice may still retain large numbers when the water is greatly contaminated with them.

Experiments showing the Effect of Freezing on Separate Species of Bacteria.—In order to find out exactly what the effect of freezing is on isolated species of bacteria suspended in water, a series of laboratory experiments was carried out by the writer as follows: A large number of test-tubes were plugged at the mouth with cotton and thoroughly sterilized. These were divided into sets, and into each tube of the different sets was put about five cubic centimetres of sterilized water which had been mixed with a small quantity of a pure culture of some well-defined species of bacteria. Before these mixtures were put into the tubes the number of bacteria contained in one cubic centimetre of the water was determined by the usual method of water-analysis. Duplicate analyses were made, to insure accuracy. Into each set of tubes a different species of bacteria was introduced. In this way we have in each set of tubes water contaminated with one species only of bacteria, and the number of these in each cubic centimetre definitely known. These tubes were now put into a refrigerator, the temperature of which was kept by ice and salt at from 14° to 30° F. The water in the tubes was usually frozen solid in a short time. The refrigerator was kept at this temperature for three months, and the tubes containing the different kinds of bacteria were taken out at varying intervals, the ice in them melted, and the number of living bacteria in one cubic centimetre determined in the usual way. By comparing the number of bacteria found in one cubic centimetre of the water after the freezing with that in one cubic centimetre before freezing, we have an exact determination of the number destroyed.

More than one hundred complete analyses were made in this way, and the effect of longer or shorter freezing studied on six species of bacteria under varying conditions.

The species used were: 1. Bacillus prodigiosus. 2. A short bacillus, frequently found in the Hudson River water and occasionally in the ice, which is apparently identical with the Proteus vulgaris of Hauser. 3. A slender bacillus very common in Croton and other waters, fluidifying the gelatin in sharply circumscribed pits. 4. The micrococcus of suppuration, called Staphylococcus pyogenes aureus, which was derived from a case of pyæmia. 5. A short bacillus very common in ice from all the sources about New York, as well as in the waters from which it is obtained. This bacillus is especially characterized by producing a beautiful greenish fluorescence in the gelatin, which it does not fluidify. We may call it for our purposes the fluorescent bacillus. 6. The bacillus of typhoid fever.

Owing to its great importance, the most extended study was made upon the bacillus of typhoid fever; more than fifty analyses having been made to determine the effect of freezing upon it under varying conditions. It does not seem necessary to give the figures obtained in each case, but, except in the cases of the typhoid-fever bacteria, to simply summarize the results obtained.

Table I.—*Bacillus prodigiosus.*

Time.	Number of bacteria in 1 c.c. of water.
Before freezing	6,300
Frozen 4 days	2,970
Frozen 37 days	22
Frozen 51 days	0

In this species it will be seen that the number of living individuals is largely reduced at first, but that a small number remain alive after more than one month. Another set of experiments on this species, whose results are given in Table IX., is interesting in comparison with this.

Table II.—*Proteus vulgaris (Hauser).*

Time.	Number of bacteria in 1 c.c. of water.
Before freezing	8,320
Frozen 18 days	88
Frozen 51 days	0
Frozen 65 days	0

Although in this set of experiments the Proteus vulgaris was completely destroyed after at least fifty-one days' freezing, this is not invariably the case, because it occasionally develops on the plate-cultures made from Hudson River and other ice in small numbers. The significance of this we shall consider farther on.

Table III.—*Slender Fluidifying Bacillus from Croton Water.*

Time.	Number of bacteria in 1 c.c. of water.
Before freezing	800,000
Frozen 7 days	0
Frozen 18 days	0
Frozen 38 days	0
Frozen 47 days	0

This species also, while completely destroyed by the artificial freezing, is occasionally found in considerable numbers in natural ice from all sources.

Table IV.—*Staphylococcus pyogenes aureus.**

Time.	Number of bacteria in 1 c.c. of water.
Before freezing	Innumerable
Frozen 18 days	224,598
Frozen 20 days	46,486
Frozen 54 days	34,320
Frozen 66 days	49,280

The culture from which this series of experiments on Staphylococcus was made was fresh and actively growing on agar. Another similar series was prepared, but from an old and partially dried agar-culture. In this the original contained 162,000 bacteria to one cubic centimetre,

* Compare Table VIII.

which grew readily on the gelatin plates. The tubes stood in the refrigerator unfrozen over night, but froze early in the morning. When examined after being frozen five and seven days, not a single living bacterium was found.

Lübbert[10] has recently shown that all the individuals in a gelatin culture of Staphylococcus are not killed by twenty-four hours' freezing. The individuals in a four weeks old agar culture were all destroyed after twenty hours' freezing.

TABLE V.—*Fluorescent Bacillus from Hudson River Ice.*

Time.	Number of bacteria in 1 c.c. of water.
Before freezing	Innumerable.
Frozen 4 days	571,560
Frozen 11 days	520,520
Frozen 51 days	183,040
Frozen 65 days	10,978
Frozen 77 days	85,008

In this species, as will be seen, there is considerable variation in the vulnerability of the individuals, as the number destroyed by freezing does not uniformly increase as the action of the cold is prolonged. This is not surprising, however, when we reflect that, although coming from the same culture, the individuals in the culture would vary both in age and nutritive conditions and that the chances are altogether against an equal distribution in the different tubes of hardy and vulnerable individuals.

This, it will be seen, is not exterminated like the previously examined species, and its invulnerability is also shown by the great frequency with which it occurs in our New York ice.

TABLE VI.—*The Bacillus of Typhoid Fever.*

Time.	Number of bacteria in 1 c.c. of water.
Before freezing	Innumerable.
Frozen 11 days	1,019,403
Frozen 27 days	336,457
Frozen 42 days	89,796
Frozen 69 days	24,276
Frozen 77 days	72,930
Frozen 103 days	7,348

The culture from which the above series of experiments was made was actively growing on agar. As the original number was so large the percentage rate of destruction is not evident, nor does it appear what the effect of the first few days' freezing is. For these reasons another series was prepared from an active gelatin culture, which gave the following results :

TABLE VIA.—*Bacillus of Typhoid Fever.*

Time.	Number of bacteria in 1 c.c. of water.
Before freezing	378,000
Frozen 12 hours	164,780
Frozen 3 days	236,676
Frozen 5 days	21,416
Frozen 8 days	76,032

The experiments on the typhoid bacillus of Table VI. were repeated, using about the same quantity of the contaminating mixture but replacing the distilled, sterilized water with the sterilized Croton, which contains more organic matter and which, therefore, more nearly approaches the conditions of natural ice. As was to be expected, however, the results were essentially the same. With innumerable bacilli in one cubic centimetre before freezing, after being frozen solid for sixty-five days one cubic centimetre contained 26,950 living bacteria.

We thus see from the experiments on this most important species, that after prolonged freezing a considerable number of the bacteria remain alive.

Billings[11] has recently shown that all the individuals in a typhoid bacillus culture suspended in water are not killed by being frozen over night.

A series of experiments was made by sowing on gelatin plates, side by side, the bacilli of typhoid fever which had just been frozen in water and those taken from a fresh gelatin culture. These invariably showed that the growth of the frozen bacteria was at first much slower than that of the unfrozen, but when the colonies were once fairly started they went on at about an even rate of growth.

EXPERIMENTS ON THE ALTERNATE FREEZING AND THAWING OF BACTERIA SUSPENDED IN WATER.—The fact that a very considerable reduction in the number of viable individuals occurs at the first freezing, while a more gradual destruction goes on as the low temperature is maintained, is doubtless due to the killing off at once of the more feeble bacteria. Still it would be interesting to know whether the marked rate of destruction is due to this factor alone, or whether the sudden change of temperature may not have a greater effect than a simple prolongation of the unfavorable condition when once the organisms have accustomed themselves to it.

With a view of throwing light upon this point a series of experiments was executed, the results of which are shown in the following tables. A number of tubes of sterilized water were inoculated with the same number of bacteria from the same source—a fresh, actively growing gelatin culture of the typhoid bacillus. A part of these were frozen solid at once, and remained so until they were removed from the refrigerator, one by one, at varying intervals, and the number of living bacteria in each determined. The second set of tubes was treated in the same way, except that the water was repeatedly frozen and thawed before examination, the number of times this thawing was repeated varying with different tubes, as shown in the table.

TABLE VII.—*Result of Alternate Freezing and Thawing on the Typhoid Bacilli—Fresh Active Culture.*

	Frozen solid and remained so.	Frozen solid, but repeatedly thawed and immediately refrozen.	
Time.	Number of bacteria in 1 c.c. of water.	Number of times thawed and refrozen.	Number of bacteria in 1 c.c. of water.
Before freezing	40,896	.....	40,896
Frozen 24 hours	29,780	3	90
Frozen 3 days	1,800	5	0
Frozen 4 days	950	6	0
Frozen 5 days	2,490	6	0

Similar experiments were made with the Staphylococcus pyogenes aureus and with the Bacillus prodigiosus, with the results shown by the following tables :

TABLE VIII.—*Result of Alternate Freezing and Thawing on the Staphylococcus pyogenes aureus—Fresh Active Culture.*

	Frozen solid and remained so.	Frozen solid, but repeatedly thawed and immediately refrozen.	
Time.	Number of bacteria in 1 c.c. of water.	Number of times thawed and refrozen.	Number of bacteria in 1 c.c. of water.
Before freezing	111,782	.....	111,782
Frozen 15 minutes	52,500	.....	.....
Frozen 2 hours	21,300	.....	.....
Frozen 24 hours	22,690	1	13,495
Frozen 48 hours	6,460	3	110
Frozen 96 hours	6,155	4	0

TABLE IX.—*Result of Alternate Freezing and Thawing on the Bacillus prodigiosus—Fresh Active Culture.*

	Frozen solid and remained so.	Frozen solid, but repeatedly thawed and immediately refrozen.	
Time.	Number of bacteria in 1 c.c. of water.	Number of times thawed and refrozen.	Number of bacteria in 1 c.c. of water.
Before freezing	339,516	.....	339,516
Frozen 24 hours	36,410	1	2,570
Frozen 30 hours	41,580	2	275
Frozen 48 hours	14,440	3	15
Frozen 96 hours	4,850	4	0

These experiments on the bacillus of typhoid fever, Staphylococcus pyogenes, and Bacillus prodigiosus show that the greatest destruction occurs during or shortly after the sudden reduction of temperature to the freezing point of water, and that if after this the bacteria remain in the ice a comparatively gradual destruction goes on; but that if now the bacteria be thawed out and immediately refrozen another large increment is destroyed. In this way, by repeated freezings and thawings, the bacteria may be completely destroyed in a short time.

It would seem that at the time of freezing a certain number of the bacteria are killed outright, while the vitality of the remainder is considerably reduced. Now if these bacteria with reduced vitality are placed under favorable conditions of temperature and nutrition, as in the culture-gelatin, they can grow and proliferate in the usual way, while on the other hand they have not vitality enough to resist subsequent freezings.

The conditions under which the last series of experiments on the freezing and thawing of bacteria was carried out differ from those which have preceded them in that, in order to hasten the freezing, the tubes were immersed directly in a mixture of ice and salt, which gave an average temperature of from 2° to 5° F. below zero, so that they were frozen at once. They were then placed in the refrigerator, where the temperature was just below 32° F., and kept here with those which remained solidly frozen until they were again thawed or removed for examination. The ordeal was therefore in this series of experiments much more severe than in any of the others. A comparison of the general destruction-rate of bacteria frozen at this low temperature and those frozen at a higher degree shows, as would be expected, a considerably larger destruction-ratio with the lower temperature. This may have a practical bearing, for it may well be true that Maine ice and Norwegian ice, which is largely used in England, may be much freer from living bacteria on this account.

Experiments on the Effect of Low Temperatures on Bacteria Suspended in Water when the Water does not Crystallize.—A very considerable destruction of bacteria of various species takes place if the water be placed in a very cold place, but kept just above the freezing-point. Thus, in a considerable number of experiments, a much larger number of individuals was destroyed in tubes in which the water did not freeze, although kept several degrees below the freezing point, than in those in which it became solid. These conditions were obtained by coating the inside of a number of test-tubes with sterilized sweet-oil, and then putting into them the water containing the bacteria. These tubes, together with others prepared without the oil, were placed side by side in the refrigerator. After a few hours, the water in the larger part of the tubes whose sides had been rendered quite smooth by the coating of oil would be found unfrozen, while that in the others would be solid. This difference is obviously in accordance with a well-known physical observation, *i.e.*, that fluids crystallize more readily when in contact with rough than smooth surfaces, and that small quantities of water kept perfectly still may be carried considerably below the freezing-point without solidifying. The previous boiling of the distilled water used in these experiments, by the removal of its contained air, contributes to the avoidance of freezing at low temperatures.

As an example of these experiments, which are not given here in detail as they do not concern directly the present study, tubes were placed side by side in the refrigerator which both held water containing the staphylococcus, 111,782 to the cubic centimetre; one tube was oiled within, the other not. After eighteen hours, during which they were kept perfectly quiet at from 15° to 28° F., the water in the oiled tube was fluid, in the other solid. Analysis showed that the water which had frozen contained 81,940 living bacteria to one cubic centimetre, while that in the other tube, which had not frozen, contained 16,400 to one cubic centimetre. Even the very hardy fluorescent bacillus can be readily destroyed if the water in which it is diffused is thus reduced to a very low temperature, but kept from crystallizing.

In these experiments the tubes must be removed carefully from the cold chamber if the temperature is very low, lest they should suddenly crystallize from sudden jarring.

This difference in the destructive capacity of what may be called dry cold and moist cold is interesting in view of the similar difference which exists at the other end of the thermometric scale, between moist and dry heat.

Summary of the Effect of Low Temperatures on Pure Culture of Bacteria Suspended in Water.—The laboratory experiments thus far recorded on the action of prolonged low temperatures on various species of bacteria suspended in water and frozen show, so far at least as the species employed are concerned: 1. That a considerable number of the bacteria are, in all cases, killed by freezing. 2. That the number killed depends upon the condition of vitality of the individual at the time of freezing. If the vitality is lowered, as by the exhaustion of nutriment in the culture, drying, etc., a larger proportion will be destroyed than if the nutrient and other conditions preceding the freezing are favorable. 3. That different species differ widely in their power of retaining life at the temperature at which water freezes and below. While some species, such as Bacillus prodigiosus, Proteus vulgaris, and the fluidifying water-bacillus, are nearly completely or entirely destroyed after a comparatively short freezing; others, such as the fluorescent bacillus, the Staphylococcus pyogenes, and the typhoid bacillus are so tenacious of life that a large number of the individuals may remain capable of growth even after long periods. This is especially significant, for obvious reasons, in the case of Staphylococcus and the typhoid bacillus, which are capable of producing serious disease. 4. That the time during which the low temperature is maintained is of importance in determining the number of bacteria of any given species which will be destroyed. For, so far as the experiments have gone, it appears that after the first freezing, at which time the destruction seems to be most extensive, a more gradual death of individuals occurs as time goes on. What the limits are to this gradual destruction does not appear from these experiments, as they have been extended only to the one hundred and third day in the case of the typhoid fever organism. 5. The unequal percentage destruction which, as appears in the tables showing the action of cold on different specimens of the more resistant species, shows that in a given culture the individuals are not equally capable of resisting the effects of low temperatures. This is what would be expected when we remember that in an actively growing culture of any bacterial species the age of the individuals, as well as the conditions favorable to their nutrition, will vary widely on account of their massing together as the growth of the colony proceeds. 6. By alternate freezing and thawing bacteria are more largely destroyed than when exposed to a sustained low temperature. If a low temperature be maintained in the water, while the latter is not permitted to freeze, a greater destruction occurs than when crystallization occurs.

It should be noted here that in these experiments on the artificial freezing of the bacteria that the test is considerably more severe than that to which the bacteria are subjected under the ordinary natural conditions of river and lake waters in this latitude, because the change of temperature is more abrupt, and at times the cold more severe. It was found impossible, with the facilities at the writer's command, to maintain a uniformly low temperature, as for a time after the refrigerator was restocked with ice and salt the temperature would fall to 14° F. and gradually rise to just below the freezing-point of water.

The importance of this change of temperature will be more evident when we see the results of the next series of experiments.

Experiments on the Artificial Freezing of Natural Waters containing Bacteria.—While, by the above method of experimentation on single species of bacteria from pure cultures, we can obtain much more precise knowledge of the effects of freezing than in any other way, there is a good deal of practical importance in knowing about what percentage of the mixed bacteria as they occur in natural waters are destroyed in the formation of ice. Now the examination of the water from a given pond or river, and the ice formed from it in the natural way, does not, even if the water be taken in winter when the ice is forming and both are taken from the same place, give a very accurate destruction-percentage, because the water beneath is always more or less in motion, and in both water and ice there is a very unequal distribution of the bacteria. Thus we might have a sample of ice which contained either a much greater or a much smaller number of bacteria than that present at the time of collection.

Approximate accuracy may, however, be obtained by collecting, under suitable precautions, waters from various sources in winter, and, after determining from each sample the average number of bacteria, freezing the remainder, and, after analyzing the ice, comparing the results.

This the writer has done, choosing as types of water samples from: 1. A large, fairly good water-system of ponds, lakes, and larger and smaller streams—namely, from the Croton water as delivered through the pipes during November, December, January, and February of the winter of 1886–7. 2. Van Cortland Pond, a small, comparatively still, shallow pond, fed by springs and small streams. This water was collected in January, 1887, from beneath the ice near the outlet and at the upper end of the pond. 3. The Hudson River, a large tidal stream, with abundant sewage pollution. The water from this source was taken in January, 1887, from beneath the ice just off Kingston Point, which projects far out into the stream. This is not far from fifty miles below Albany, and at the time of collection the tide was ebbing. This would seem to be a fair sample of water from the lower Hudson.

All of these samples were collected by the writer in small sterilized bottles, such as are usually employed for this purpose. Immediately after collection the samples were brought to the laboratory and the examination at once begun. In the case of the Hudson River water three hours passed in the journey home, but the water in the mean time was kept cold. This is important, because the possibility of a multiplication of the bacteria in transit would seem to be excluded.

3,448	16	324	3,056	6	200

The numbers of bacteria killed by freezing, as will be seen, vary so much in different samples and even in different specimens of the same sample that we can arrive in this way only at very general results. This variability depends largely, as would seem from the above series of laboratory experiments, upon the varying number of different species of bacteria which any given sample contains, as well as upon the varying degrees of vulnerability of individuals of the same species. We may, however, say in general that water containing bacterial contaminations by freezing, and remaining frozen for a few days, may purify itself by the destruction of as much as ninety per cent. of the bacteria. Furthermore, the number of living bacteria is gradually reduced in the ice as time goes on, but that this reduction does not go on to extinction, for all species at least, will be seen from the analyses of natural ice which are to follow.

Having thus established experimentally a variety of facts regarding the purification of water from its bacterial contaminations by freezing, let us now turn to the natural ice which is supplied to New York City from various sources.

Description of Sources of the Ice-supply of New York City.—The ice which is supplied to New York City, and to a certain extent to Brooklyn and Jersey City, comes almost entirely from three sources—from the Hudson River, from a few lakes and ponds adjacent to the Hudson or near the line of some of the suburban railways, and from Maine. The Hudson River stands foremost as a source of supply, the outlying lakes and ponds furnishing in comparison but a moderate quantity, while the Maine supply is drawn upon, as a rule, only when the ice season in this region has been a poor one and the domestic stock runs low. The competition in the ice market is so sharp and the margin of profit usually so close that the increased cost of transportation from Maine and the liability to wastage in transit are sufficiently potent factors to largely shut the Maine product out of competition if plenty of ice is in storage nearer by.

The total storage-capacity of the ice-houses along the banks of the Hudson from Troy to Poughkeepsie reaches the enormous amount of more than three million tons. The storage-capacity of the houses which draw their supply from lakes and ponds near New York is about three hundred and forty thousand tons. Besides this, in good ice years a considerable quantity is frequently stacked outside the houses for use early in the season.

Let us now look more closely at the bodies of water from which the New York ice-supply is obtained, and first at the lakes and ponds.

Among these *Rockland Lake* stands foremost both in the popularity of its ice and the quantity which it furnishes. The traveller by the New York Central Railroad, looking from the car-windows across the river at Sing Sing, will usually see clustered at the foot of the cliffs a number of white, clumsy craft with slender derricks and awkward windmills set upon their decks. These are ice-barges. Just over the summit of the hill at this point lies Rockland Lake, a lovely sheet of water set in a little basin on the western slope of the hills

which thrust themselves forward into the river here and form the upper limit of the Tappan Zee.

The lake is in part shallow, but in some places has considerable depth; its shores are open, and the water is supplied almost entirely from springs which drain the hill-sides surrounding it on the north, east and south, those on the east or river side sloping abruptly down to its shore. It is a lake, the situation and general appearance of which would impress the writer with its natural fitness for a source of water- or ice-supply.

The ice is stored in large houses on its banks, and these have a capacity of about one hundred and fifty thousand tons. During the shipping season the ice is loaded into cars at the house, drawn by steam up a short incline and lowered down a longer incline on the river side of the palisade to the barges.

A little village lies in the break in the hills over which the inclined railway passes, and, unfortunately, some two-score of small dwellings with the ordinary outhouses are built on the steeply sloping hill-side which extends, only a few rods away, to the edge of the lake.

The possibility that the drainage from these dwellings may reach the lake without that thoroughness of soil-filtration which a strict attention to hygiene demands, seems worthy of consideration. The lake is used for boating in summer and for skating in winter.

Swartout Pond.—On the little brook which carries the surplus water from Rockland Lake off into the Hackensack River lies this small, shallow pond. The shores are for the most part clear and open, and the ice-house has a storage capacity of about fifteen thousand tons.

The ice gathered from these two sources is of especial value to the company controlling them, owing to their nearness to New York and the facility of transportation by rail or water during the cold months when the river above is frozen and navigation is at a standstill.

Highland Lake.—This little picturesque body of water, perched on the hill-side just below Fort Montgomery, and supplied by springs from the high, wooded hills which lie behind it, is an ideal source of ice-supply. No dwellings, barns, or other sources of contamination are near it, and the water is deep and clear.

The ice is run from the shore of the lake directly down a series of inclines into the storage houses beside the West Shore Railroad and the Hudson River, so that by the force of gravity alone the ice may be carried from the lake to the houses and thence to the cars or barges. A considerable stream runs from the lake in winter. During the months in which this investigation was in progress, ice from this source was not being delivered in New York, and hence no analyses were made of it. Like most pond and lake ice, it usually contains numerous scattered bubbles, but its source is so clean and pure that there seems every reason to rely upon its excellence.

Pond on Verplank's Point.—Here, some twelve years ago, a large swamp, through which ran a small brook draining the region toward Montrose, was converted into a shallow pond by a low dam built just at the river's edge. The water-level in this pond stands some feet above that of the Hudson River at high water, and a sluice-way, controlled by a gate, allows of the nearly complete emptying of the water. In the autumn, when, as the writer's informant graphically expresses it, "the pond has got done purging itself"—by which is meant the collection of dirty scum and a variety of dead vegetable matter on the surface after the hot weather—the water is drawn off, and the pond fills anew. A small quantity of water runs over the sluice-way in winter, and no sources of contamination were observed on the shores. The pond is called "Lake Meahaugh," and the storage-capacity of its houses is about sixty-five thousand tons.

Ice Pond or Hinkley's Pond (so-called "Croton Lake").—This shallow pond, covering a few acres, lies on the line of the Harlem Railroad, between Dykeman's and Towner's, a little more than fifty miles from New York. The pond is mainly supplied by springs from the surrounding hills, but there is a small inlet and a small outlet, which forms one of the sources of the Croton River. The banks are open and free from trees, and, with the exception of the ice company's barn, free from buildings or other obvious sources of outside contamination.

The pond was apparently at one time considerably larger than it is at present, but its lower end has become filled and is now a swamp, in which water at the level of the lake surface is standing, and out of which comes a bushy undergrowth and a considerable number of small, stunted trees. This feature is important, as the pond-water, although open and drained by a small running stream, is indirect connection with—is, in fact, a part of—a large swamp containing much stagnant water.

Van Cortland Lake.—This small lake, or, more properly speaking, pond, lies about four miles above High Bridge, on the line of the New York City & Northern Railroad, and within the limits of the new Van Cortland Park. It is not very deep, and is of a few acres in extent. The water is held in place by a small dam furnishing power for an old grist- and saw-mill, and is used for ice-cutting and skating purposes in winter, and, to a certain extent, for boating in summer. Its banks are open and apparently tolerably free from external sources of contamination.

There is a small overflow, and the water is supplied in part from springs, in part from small streams, one of which runs through a long woody swamp, which is in communication with the pond at its upper end. The ice-houses hold about seven thousand tons. While much of the ice cut here is delivered in the upper part of the city, its nearness and situation on the railroad make it available for a winter supply to dealers whose stock on the Hudson is cut off by the close of navigation, and a varying quantity is shipped to New York and other places without housing.

Tuckahoe.—The Bronx River, at the village of Tuckahoe, is dammed, to furnish a part of the power for a rubber mill located here, and the small, rather shallow pond which sets back and eastward to the Harlem Railroad, supplies ice for the houses, containing about twenty thousand tons, and for direct shipment in winter.

Ice from this source, together with that cut on Ice Pond, furnishes the so-called "Croton Lake Ice." *

The Tuckahoe Pond shares in the virtues and faults of the lower Bronx, which passes several villages above. A suitably authorized system of inspection would doubtless suggest the desirability of placing the ice company's barn at a greater distance from the shore of the pond, and the removal farther from the water's edge of three out-houses belonging to dwellings near by. It should be added, however, that the vaults of these out-houses are said to be cemented.

Lake Mahopac.—On this lake arrangements have been made for ice-harvesting, and a large house, capable of holding about thirty thousand tons, stands beside the New York City & Northern Railroad, within easy distance of the lake. The ice from this source is not, however, at present in the market, owing, as the writer is informed, to the cost of transportation to New York. Its quality was therefore not investigated.

There are also harvesting facilities at Greenwood Lake.

The Hudson River.—We now come to the great and most important source of our ice-supply—the Hudson River. We should remember at the outset that this majestic stream is, in fact, a great estuary of the sea, and that its impressiveness as a large body of water and its importance in navigation are largely due to its tidal connection. The water is brackish at times as far up the stream as Poughkeepsie, and the influence of the

* No ice is cut for the market on the reservoir lake known in the geographical sense as Croton Lake.

tide is felt by a rise of more than a foot at Albany. The fall of the river from Albany to New York is so slight that at times the current at Albany is reversed and runs northward for some hours.

The main ice-harvesting fields lie between Poughkeepsie and Troy, and their exact location within these limits is determined by a variety of conditions, such as dockage facilities, currents, widenings in the river, ownership of water-front, etc. The water must be deep enough, so that the ice will not be contaminated from the bottom by grass, sand, etc. Areas of water in which the currents are not too strong are sought after, as during mild winters the requisite thickness of ice is more certain to form where the currents are not excessive. In prolonged cold weather, however, the river freezes completely over, so that ice may be cut in the deeper channels as well as elsewhere.

The river is, at best, rather shallow for purposes of navigation in its upper portions, and large quantities of detritus, which are annually brought down the stream, cause a constant and often considerable change in the bottom, so that each spring the river must be resounded and buoyed. A glance at the map of the upper part of the region which concerns us, say from Coxsackie to Albany, or even a study from the car-windows, shows in the river a very large number of large and small, low, irregular islands scantily covered by a stunted vegetation.

These islands, a gradual formation from sedimentary deposit, indicate the shallow character of the stream, which, in this region, is virtually a long, narrow archipelago. An extensive system of dikes has been built for the purpose of deepening the navigation channel, and behind these lie large areas of comparatively still water.

Let us now look at the character of the water which the Hudson bears within the limits of the ice-harvesting region. At the upper part of this section is Troy, a city of over fifty thousand inhabitants, emptying its eight million gallons of sewage daily into the river, already charged with contributions from Cohoes and Lansingburg, to say nothing of the impurities which the Mohawk brings with it from the west. A few miles below Troy lies Albany, with over ninety thousand inhabitants, and an efficient sewage system which pours directly into the river. These are the great sources of pollution of the river water.

Hudson with over eight thousand inhabitants, Catskill with more than four thousand, and Kingston with more than eighteen thousand, add their greater or less sewage contributions within the ice-field limits, to say nothing of numerous smaller towns which drain into the river.

It would seem hardly necessary to do more than mention the fact that a city of the size of Albany empties its sewage into a stream whose waters a short distance below are used in the form of ice for drinking purposes, unfiltered, to cause a universal condemnation of the practice. It is estimated by Mr. Sweet, as quoted by Dr. Chandler in his report on the water of the Hudson River in January, 1885, that the average daily flow of the Hudson at Albany amounts to 6,677,000,000 gallons. The amount of water pumped from the river for the use of the city of Albany amounts, on the average, to 6,064,000 gallons daily. This, of course, is largely returned to the river as sewage. The Hudson River just below Albany thus consists of about 1,100 parts of rather dirty river water from Troy, and one part of Albany sewage. A series of chemical analyses by Mason, made at the request of the Board of Health of Albany, showed: "First, the influence of the addition of Troy sewage is felt in the river just below Troy; second, there is no material change for the better by the time the water reaches Albany."[12]

A slight conception of the enormous number of bacteria of various kinds which are brought into the river with the sewage may, perhaps, be gained, if we remember that Sucksdorff[13] found, by a long series of experiments on healthy men with an ordinary mixed diet, that in an average from fifteen days' experiments the number of bacteria discharged daily from the body was more than fifty-three billion. Albany, it will be remembered, has a population of ninety thousand persons.

Rosenberg[14] found that the effect of the sewage of the city of Würzburg, on the River Main, so far as the number of bacteria is concerned, was to increase the number of living bacteria more than twenty times.

But if one should require more proof of the filthy condition of the Hudson just below Albany, he has only to stand on some summer or autumn day, when the tide is at the ebb, on the shores of the Albany Basin, a walled enclosure containing some thirty acres made for the purpose of increasing the city dockage, and into which fifteen sewers empty, carrying the waste of over thirty thousand people. Under these circumstances the observer will certainly be rewarded with both ocular and olfactory evidence of a most convincing nature.

Still, a certain proportion of New Yorkers have gone on amiably consuming their distant neighbors' filth under the impression, when it was thought of at all, that water purifies itself from its contaminations in freezing. That it does so, so far as its most important ingredients, the bacteria, are concerned, in but a partial degree the investigations above recorded and those about to be set down abundantly show.

And yet, within sight of the walls of the Albany Basin, down the stream, stands one of the houses, with its sewage-laden ice-field, in which this delectable harvest is stored for the comfort of a considerable number of New Yorkers. It was from this region that the ice which was actually being distributed in an outlying district of this city was taken, which, as will be seen below, contained from twenty thousand to fifty thousand living bacteria to one cubic centimetre—that is, to about one-third of a teaspoonful. It is interesting to note that arrangements are made for storage at this point of about twenty-five thousand tons of this ice, and some of it is beautifully transparent.

The first large house stands about four miles below Albany, and below this, in rapidly increasing numbers and capacity, the ice-houses are scattered along the river, always in the vicinity of the water on which their ice is cut. It is only justice to the reputable ice-harvesters and dealers to say that, so far as the writer is aware, they entirely condemn the practice of ice-harvesting in the immediate vicinity of Albany.

If we make an approximate estimate of the amounts of ice for which storage-capacity exists within six-mile reaches below Albany, we find that within the first six miles there is cut and stored in favorable seasons at least 215,000 tons; within the second six miles, 519,000 tons; within the third 328,000 tons; within the fourth, 382,000 tons; within the fifth, 438,000 tons; within the sixth, 71,000 tons; within the seventh, 254,000 tons; within the eighth, 318,000 tons; within the ninth, 198,000 tons; within the tenth, 95,000 tons. That is, about two-thirds of the ice is cut within thirty miles of Albany, and nearly one-fourth is cut within twelve miles.

Spontaneous Purification of the Hudson River Water.—A good deal has been said, and some of it in a very indefinite way, about the capacity of rapidly flowing streams to purify themselves from sewage contamination, particularly if the quantity of freshly added pure water is large in proportion to the amount of contamination, and there is no doubt whatsoever that a great deal is thus accomplished if the conditions be favorable. But it should be borne in mind that the experience which has been gathered during many years of painstaking investigation on the subject of water impurities and spontaneous purification by oxidation, etc., has been largely based on the results of chemical analysis and the deductions for the most part drawn from it alone. The ammonia and the nitrates and nitrites, which, to the chemical analyst are the exponents of the water's impurities, are simply the products engendered by the life-processes of bac-

teria, which are, in the majority of cases, themselves present, though undetected in the water analyzed. Now, nothing is more definitely established than that water can and does free itself under favoring conditions, such as exposure to air in running streams, etc., from these organic impurities. That the same conditions destroy the bacteria, which are, after all, so far as we know, the more important active agents in the diseases produced by bad water, has not yet been demonstrated in a sufficiently comprehensive way.

But the conditions in the upper Hudson are peculiar. A river of considerable size, receiving a rather dirty tributary in the Mohawk, reaches Albany contaminated with sewage from Troy. To this comes the sewage of Albany with its ninety thousand souls. That this river, large as it is, must be filthy here would seem hardly to need the demonstrations of science to make clear. In its first twelve miles below Albany it flows through a great, long, narrow archipelago, lies more or less stagnant behind the islands and dikes, and is met, the sewage still pouring in above, and its current reversed by each incoming tide. Below New Baltimore the river channel is more open, but the retarding influence of the tides is still more marked.

Moreover, the sewer-laden water of the upper Hudson, as soon as the ice commences to form, is covered above from contact with the air, and is virtually in the condition of a great closed conduit.

On the other hand, it should not be forgotten that in the comparatively still water behind the islands and dikes there is given tolerable facility for sedimentation of the bacteria, by which means, as experiment shows, a considerable proportion of bacteria may be removed from the upper strata of the water.

The marked effect of the subsiding reservoirs in use in England and elsewhere in freeing the water from various impurities is noteworthy here. Numerous experiments have shown that when water containing bacteria is placed in vessels which are kept quite still the bacteria may settle toward the bottom so completely as to free the upper strata even to the extent of over ninety per cent.[1]

It is these latter considerations which warn us against an unqualified condemnation of the Hudson River water for ice purposes, since only a careful series of experiments can show at what distance below the source of pollution the water may have so far freed itself from bacteria, if it do so to any considerable degree, as to render it fit for ice-harvesting purposes. In the mean time we must have recourse to biological analysis of the ice itself and see to what extent bacterial contaminations actually exist in the ice harvested in various parts of the river.*

Natural Ice Examined—Sources, Appearance, Mode of Formation, etc.—It was necessary for the purposes which the writer had in view in the prosecution of these studies to know with certainty exactly where the sample of ice to be examined came from, and it became evident at the very commencement of the work that to obtain samples from the wagons which deliver ice through the streets would lead to very uncertain results. These ice-wagons are mostly loaded either from barges on the water-front or from the cars, or from platforms at these places.

Each day's supply may come from more than one source, and these may be entirely unknown to the drivers, who are, moreover, apt to be somewhat reticent as to the exact source of their ice, and not infrequently positively deceptive in the accounts which they give of its origin, at least to the inquiring scientist. The names on the wagons are, furthermore, not altogether to be relied upon, as a rule, as indicative of the exact source of supply, since there is a good deal of speculation in ice and exchange of proprietorship before the product comes to the market. Then, too, a not inconsiderable degree of fancy is exercised in the choice of the name which, in some cases in large letters on the sides of the ice-wagons, would naturally indicate to the consumer the source of his supply, but is, in fact, in many cases entirely misleading. For these reasons the ice for the present studies was in all cases obtained either directly from the barges or canal-boats or cars, the exact source of whose cargoes could be accurately ascertained, or from certain houses the origin of whose ice was known by the writer, or was obtained on the spot of its harvesting by the writer or his emissaries.

Let us now see what the biological analysis of our New York ice shows. I have made over 270 complete analyses of samples taken from different blocks of ice at different times, so as to insure a fair sampling of the product. These specimens were mostly from 1886 ice, but a considerable number were from the 1887 harvest. Their sources were as follows: 153 from the Hudson River, at various points from West Park to the vicinity of Troy, embracing samples from all the more prominent fields and many of the smaller ones; 22 from Rockland Lake; 23 from Swartout Pond; 51 from ice-pond, so-called "Croton Lake;" 5 from Maine; 6 from Verplank's Point; 8 from Tuckahoe; 9 from Van Cortland. Besides these were a number of other samples from these and various other sources, examined for special purposes and not tabulated here.

Now, taking the results of all these analyses of ice from the various sources, we find that the average number of living bacteria contained in one cubic centimetre of the melted ice is 2,033. Or, to express the estimate in more common terms, an ordinary drinking-glass containing half a pint of the melted average ice would harbor about half a million living bacteria of various kinds. He who, impressed with the importance of a pure drinking-water, should perfectly filter half a glass of average winter Croton water, and then add to it an equal quantity of the average ice, would have the satisfaction of replacing the bacteria removed with more than eight times as many from much more uncertain and questionable sources.

But a simple statement of these aggregate numbers, true though they be, gives a very imperfect and, it may be added, a very misleading conception of the real significance of affairs. Such general statements are misleading, if made without further qualification: First, because they do not indicate what proportion, if any, of the bacteria are probably harmful; second, because ice from various sources may contain differing quantities of bacteria; and, finally, because, as will presently be shown, the different parts of the blocks of ice as they come to the market may present very great and important differences in the number of bacteria which they contain. We have, therefore, to examine more in detail the result of the ice-analyses, and we will look first at the distribution of the bacteria in the blocks of ice.

(To be continued.)

Bronze Statue to a Physician.—Italy, more than any other European country, is lavish of honors to her great physicians and surgeons. Francesco Puccinotti, the classic historian of medicine, the translator of Aretæus, the acutest intellect ever applied in Italy to medical jurisprudence, author of memorable treatises on epidemics peculiar to the nineteenth century, and in all respects exemplary as a citizen, is about to receive in the Santa Croce of Florence (the Walhalla of distinguished Italians) the tribute of a monument in bronze. Urbino, his native town, heads the subscription-list with 1,000 lire (£40), and the Universities of Pisa and Macerata, with the Institute of Higher Studies in Florence, are combining to augment it by their own contributions and those of other seats of learning.—*Lancet.*

---

* The writer has been particular in obtaining the facts about the Hudson River and other sources of ice-supply here described at first hand whenever this was possible, and for this purpose has seen, and in most cases carefully inspected, nearly all the important ice-houses and ice-fields on the river and lakes and ponds from which New York ice is derived. He wishes to express his indebtedness for many interesting facts about the Hudson River, its currents, dikes, shoals, etc., to Captain Jacob Schermerhorn, who for many years has buoyed the channels in the river in the Government service, and who accompanied him in the inspection of a portion of the upper Hudson.

THE MAMMARY GLAND.

By E. F. BRUSH, M.D.,

MOUNT VERNON, N. Y.

When I was at college, one of the professors told the class the following story, to illustrate the astuteness of Professor William A. Hammond: A young man lost one of his toes by a railroad accident and sued the company for damages. Professor Hammond was employed by the railroad company, and gave it as his opinion that the loss of one toe did not in any manner disable the man. The plaintiff's attorney, a rising young lawyer, in his address to the jury, referring to the testimony of the professor, asked, "Did God Almighty create any part of the human body to be of no use?" At which Professor Hammond asked the lawyer if he could tell what God Almighty had created the mammary gland in the male for. This was a telling retort, before which, the story continued, the young lawyer collapsed, and the professor's side of the case was victorious.

Now, I agree with the young lawyer, that every part of the body has its use, either immediate or remote. We in our ignorance may not be able to understand the uses or functions of some organs or members of the body; nevertheless, we may be sure they were not created for mere embellishment. The mammary gland in the male is by nature designed as a *dernier ressort* for the survival of the mammalia. If the female dies, or is for some other reason unable to furnish her young with nourishment from the breast, the duty devolves on the male parent. But under our present advanced stage of civilization, even when both parents are able to furnish nourishment, they both refuse to do so, and the task is left to the patent baby-food man, with his perfect substitutes, peptonized or otherwise, and the mammary gland is on the decline. In the ordinary course of events, we consider the breast and udder of pregnant females as the natural source of milk, but many have discovered, and accidents have revealed, that it is not limited to the female sex nor to the pregnant state. Male creatures of both the human and brute kind have secreted milk, and the virgin female has been known to secrete it also. The Roman Charity, so famous in history and painting, is a prominent illustration of the latter in the human species—where an old man, confined in a dungeon, was supplied with nourishment by sucking the breasts of his daughter, a virgin. In the time of Aristotle it was known that some men had been found to have milk in their breasts, and Cardan, upon his own knowledge, relates the same, averring that there was such a quantity that a child might be nourished by it. Pliny relates the same of a man in his time, and Aldroobad mentions another instance of the same kind. I have been credibly informed by a reputable physician of New York City of a case he was called to treat. A young lady of seventeen years, whose sister died of consumption, and left her the baby, by reason of allowing the child to sleep with her and take hold of the nipples to quiet it, found her breasts secreting an abundance of milk.

I knew of a negro man in New Jersey who raised a litter of valuable black-and-tan puppies on milk which they sucked from his own breasts. There is a well-authenticated case on record, in the English "Philosophical Transactions," of a wether sheep giving suck to a lamb, and that not wantonly, or for once, but in a regular quantity, and enough for the support of the lamb for some months. Recently a faster in England had been exciting as much interest as our own Tanner, until the newspaper reporters discovered that he was being regularly nourished in like manner to the Roman old man. I myself removed the ovaries from a yearling heifer, and, by having the teats pulled for several days, caused her to give milk. She was a virgin of the bovine race. One of the German journals, some years ago, contained an advertisement of a physician who made a specialty of furnishing nurses. He excited the secretion of milk not only independent of pregnancy, but in men as well as in women. An applicant for a wet-nurse was always asked whether a male or female was desired. Males were very often preferred, under the belief that greater vigor was thus imparted to the infant.

These facts ought to be a warning to the female sex of the present time, when the female mammary gland seems to be subsiding under the influence of the patent baby-food man. Gynecologists of to-day are spaying the human female. Even the ancients knew that the male could secrete milk; now, if someone can discover how the male can bear young, the revolution will be complete, and the mammary gland of the female be one of the glories of the past. Our duties as physicians, however, will not be lessened; we may still have the troublesome caked breast and mammary abscess, but perhaps not so many sore nipples, unless the future male nurse take to wearing corsets, thus depressing and irritating the dug. Possibly the æsthetic features will be removed from the surgery of the mammary abscess; that is, we will not allow disfigurement to deter us from using the bistoury in the most available place. Certainly this change will bring some amazing conditions with it, as all changes do. When obstetrics and gynecology become branches of science relating only to the male, the obstetrician and the gynecologist will meet in peace. No more will the section on the diseases of women be the pandemonium we are so accustomed to witness at the great gatherings of medical associations. I can see another advantage in this new approaching order of things. A doctor in Pennsylvania writes an article on mammary abscess, in the course of which he says: "Indeed, physicians are sometimes charged with not desiring to hasten recovery, inasmuch as it is an opportunity to 'run up a bill' without incurring great responsibility." Of course this refers to the female mammary abscess, but let the physician try to run up a bill by delaying recovery of a mammary abscess in the male; then, if that male amounts to anything, the physician will incur the responsibility of being knocked out in the second or third visit.

As I have had no experience in treating mammary abscess and sore nipples in the male subject, I shall have to continue my story by relating to you my experience and method of treating the female gland.

There are three varieties of mammary abscess: *First*, supermammary abscess, when the morbid process is confined to the tissues covering the gland; *second*, mammary abscess—in this the substance of the gland itself is involved in the inflammatory state; and *third*, submammary abscess, when the pathological changes are confined to the tissues beneath the gland. The two former are the most common, the latter rare and dangerous. During the puerperal state there is a degree of activity in the mammary gland that is excessive. We seldom see the flow of milk established without a distinct febrile movement; therefore, it is not strange that very slight disturbances even in other parts of the economy do excite pathological changes in the puerperal breast. I am often reminded of Newport's experiments with bees when I see the mammary gland inflaming. Heat is due to movement, molecular or otherwise, and this is beautifully illustrated by the experiment with bees alluded to. During the winter, when the external temperature was 34° F., the temperature of the hive was found to be 48° F. when the bees were quiet, but, by tapping on the hive, and thus exciting the bees into a noisy activity, the temperature would increase to 102° F. In the milking breast we have an aggregation of organisms in action. If we can keep these organisms quietly at work the temperature remains normal, and no pathological changes are induced; but a malarial chill, a rheumatic seizure, a sudden cold, and all like conditions, simulate the tapping on the bee-hive. Quiet these, and no harm ensues. I have often aborted an approaching mammary abscess that had been ushered in with a chill by giving a full dose of the sulphate of quinine, and this, in a very

few hours. Likewise, when the induration is preceded by the prodromatous symptoms of rheumatic fever, it has been checked by the administration of salicylic acid. This latter remedy has been recommended by some writers on mammary abscess without their indicating the rationale of its action. I am sure when it is of avail it is in the rheumatic diathesis. So we could enumerate many other conditions, but the foregoing are, I think, sufficient to indicate to you the necessity of searching for the constitutional disturbance that manifests itself locally in this the most active of all the glands. Very often sore nipples are the cause of mammary abscess, and even if not so, this condition itself calls for prompt curative action. I think I have seen as acute intense suffering from sore nipples as from any other cause of human pain. Thus far in my practice I have been able to cure sore nipples promptly and efficiently. Of course, it is much better to prevent them from becoming so, and this you can do if you have the patient under observation before confinement. About three months before time, cause all garments that press the nipples to be loosened. Procure two large nutmegs; with a pen-knife dig out the centre of the nut, and fashion the cavity like a nipple. These are to be worn on the nipples all day; at night place them in a vessel containing brandy saturated with alum. These will draw out the nipples if they are retracted, and with the natural oil in the nutmeg, together with the brandy and alum, will tan and likewise keep them soft, thus preventing cracking. When you have not been able to follow this prophylactic treatment, but are called on to treat sore nipples, I would recommend you to proceed as follows: Wash the nipples clean with a soft linen rag, using white castile soap; with the tip of the finger rub on the sore the least possible amount of the officinal ointment of ammoniated mercury, then cover the nipple with a small wad of oakum fashioned like a cap. Now direct the mother to nurse the child on one side only for each meal; thus, as the interval between nursings is three hours, each breast will have six hours' rest. Before nursing, caution the mother to wash off carefully every vestige of the ointment; impress on her that the ointment is poisonous. After the child has been nursed, dry the nipple carefully with talc, using plenty of it; do not, at this time, wet the nipple with water; put on again the small amount of ammoniated mercury ointment and a fresh cap of oakum. If the nipple become wet from the oozing of milk, which it is liable to do while the baby is nursing at the opposite breast, dry the nipple very thoroughly with the talc. In fact, always keep the nipple dry with talc, and covered with oakum, using a fresh piece of oakum with each change. Patients have often been delighted, as I have myself, with this treatment, and I think many of you will be equally so if you follow carefully each detail.

In the treatment of mammary abscess, if it does form in spite of you, as it often will, when the pain is very severe ice-bags will relieve quicker and more effectually than any other application. If the induration is large, involving any large portion of the breast, properly applied bandages will relieve the tension. If these bandages are applied or strapping resorted to, the entire gland must be pressed firmly and evenly. Sometimes this even, firm pressure will stop the secretion of milk, and if it does so you will be pleased to find the inflammatory condition subside without other treatment. But occasionally, in those breasts prone to suppuration, you will find an excessive flow of milk; this condition of galactorrhœa is best treated with ergot and quinine in capsules, and small repeated doses of the iodide of potassium in solution. In regard to emptying the breast of milk while treating for abscess, we must be governed by circumstances; if there is a baby in the case it is all-important to keep the gland in action. According to my experience a child can safely nurse from a breast in which there is a large discharging abscess, provided it can be done without causing too much pain to the mother. I have never yet seen pus come from the tit. I have several times seen milk discharged from a sinus in the breast. This is different with the bovine race; when an abscess forms in the udder of a milking cow the pus is discharged through the dug. An abscess opening externally in the udder of a cow must be rare, for I have never seen one. I suppose this arises from the abnormal condition of the udder caused by constant milking.

Very often it becomes necessary to empty the breast of milk to relieve pain. This is best accomplished with a soda-water bottle. Heat the bottle very hot in boiling water, wrap a cold wet cloth round the neck near the mouth, introduce the nipple into the mouth of the bottle and press against the breast as firmly as possible. As the bottle cools the suction increases, and this takes place so slowly that the suction is produced gently but is very strong. With this method I have succeeded in drawing milk from a breast when every other means had failed. Many of the breast-pumps found in the shops are simply barbarous.

If you are called on to lance a breast, do so as gently as possible, and remember that one of the glories of a woman is her breast; therefore make the incision as far out of sight as possible. Bear in mind the story of Raymond Lully, the famous alchemist, who when madly in love with the fair Eleanor of Castile had his passion forever quenched by a sight of her breast with its hideous cicatricial abscess. After you have made an opening cover it completely with oakum, bandage tightly, leave the nipple projecting through the bandage in order to empty the breast if necessary, and likewise to prevent the milk from getting between the breast and the bandage.

If you succeed in keeping a troublesome breast in a healthy condition, you will be doing a great deal toward the welfare of the infant, and also toward inducing the mother to perform her natural functions. Then the child will grow up, and in the words of the psalmist will say unto you: "Thou art he that took me out of the womb; thou didst make me hope when I was upon my mother's breast."

Clinical Department.

A CASE OF ABSENCE OF THE CRANIAL BONES.

Dr. James L. Bailey, of this city, writes: "At 8.30 P.M., January 5, 1887, I was called to attend Mrs. P——, eighteen years old, in her first confinement. On examination I found the os only slightly dilated and the membrane intact. For a time I was in doubt as to what I had to deal with, as the presenting part was unlike anything I had yet encountered. It felt like a placenta at about the fifth month, but in an hour or so I was satisfied that I had a vertex case. What the mass in front was I could not conceive; it could not be placenta prævia, for there was no hemorrhage. It might have been a uterine polypus with a long pedicle; but as labor was advancing satisfactorily, and there was no indication for interference, I determined to await events. About 3 A.M. the vulva was distended, and on inspection I discovered what was undoubtedly the brain, divided into a number of lobes, and covered with a dark purplish membrane. From the posterior aspect there was a small kidney-shaped projection. After waiting a while and finding the pains were not strong enough I delivered with the forceps, expecting another pain to bring the shoulders. In ten minutes, as no pain had come, I determined to make traction on the head, knowing that the child could not live. But traction of itself was not sufficient, so I introduced both thumbs into the rectum, and with this manœuvre delivered the shoulders. The cause of the difficulty was then apparent, as the body was developed considerably beyond the average. There was complete

absence of the crainal bones from the brows upward; the ears were situated lower than normal, and the upper eyelids looked as if a V-shaped piece had been cut from each. The penis was rudimentary and the scrotum absent. The appearance of the child was very much like the case of anencephalus shown in J. Lewis Smith's work on diseases of children, with the exception of the brain. The mother stated that about five months ago she was badly frightened on discovering, in a hotel where she was living, a woman who was almost suffocated from inhaling escaping gas. The child lived thirty hours. An autopsy was refused."

GUMMY TUMOR OF THE BRAIN.

Dr. Benjamin Edson, of Brooklyn, reports the following case: "September 16, 1886, I was called to see Mr. C. H. R——, aged forty-nine, married, and having grown-up children, apparently healthy. Found him feeble, sallow, querulous, complaining of inability to take food, or even to swallow liquids, and suffering from obstinate constipation. He had a moderate cough, and some expectoration, the significance of which was somewhat obscured by profuse salivary discharge, and also free secretion from the mucous membrane of the buccal and naso-pharyngeal cavities, due, as was alleged, to large doses of iodide of potassium which he had recently taken. I learned that for some years past he had been continually changing from one physician to another, as often as he had become dissatisfied, and this seemed to be very frequently. Some time since he was operated upon for anal fistula, after which he thought that his constipation was worse than before. He had been treated for some time for considerable trouble in his throat, which he thought was becoming paralyzed. He formerly weighed about one hundred and seventy-five pounds, but had now fallen to about one hundred and thirty. He readily admitted that he had primary syphilis in 1860. There were marks of an old specific ulcer on the left leg; anæsthesia on the outer aspect of both limbs, particularly below the knees. There was necrosis of the turbinated bones on the right side of the nose. He said that he had been salivated by the use of mercury some years since, and would under no circumstance ever again take either mercury or iodide of potassium. There was a peculiar hesitancy in his speech, which he attributed to a short uvula, which he claimed had been burned off by some experimenting doctor. Careful observation, however, showed that the trouble was not in the vocal organs, but that there were brief recurring intervals during which the action of the brain was apparently arrested, cerebration for an instant being in abeyance. Both pupils were dilated, the right much more than the left. Further investigation showed that some time ago he began to omit words while writing, though for a time he was able to discover and correct his omissions. More recently he failed to discover his errors on perusing what he had written. In conversation he had no interest in anything that did not relate directly to himself; was intolerant of any opinion not fully in accord with his own, and manifested the symptoms and behavior of hypochondriasis, or more properly, perhaps, of syphilophobia. The diagnosis was made of syphilitic tumor of the brain, and a bad prognosis was given, especially as he refused to take longer *the* remedies from which alone relief could be expected. Although on one occasion he readily swallowed one-third of a gobletful of medicated water, he still insisted that he could swallow no nourishment, solid or liquid, on account of the obstruction in his pharynx. I examined his throat carefully, and assured him, unwisely as it proved, that there was nothing to prevent his swallowing, if he chose to do so. This proved to be the turning-point of my influence with him, which was now practically at an end. After a few days of persistence in starving, and refusal of treatment, he again wanted a change of physicians, and I gave up the case to Dr. George A. Ostrander. Under Dr. Ostrander's care he proved no more tractable, still refused food and medicine, and he finally died quietly on October 8th. He left a request that there should be a post-mortem examination of his body.

"Dr. A. W. Shepard, who had seen him once in consultation, performed the autopsy five hours after death. Present, Drs. Ostrander and Edson. Rigor mortis had not set in. The skin was sallow and shrunken. Muscles rather firm and quite well developed. Kidneys, heart, and spleen normal. Right lung completely broken down; costal pleura adherent; pleural cavity occupied by fibrous shreds and dark grumous fluid. Surface of left lung dotted over with dark, almost black, spots of the size of a silver three-cent piece. In the upper lobe was a large cavity or cicatrix, with fibrous elastic walls resembling gutta-percha, but inclosing no cheesy or calcareous material. It showed a very satisfactory arrest of the active trouble at one time existing in that lung. Dura mater but slightly adherent. Cerebral vessels on the surface distended to their full capacity, appearing as though forcibly injected. Pia mater very cloudy over the entire surface of the brain; no tumor apparent. On removing successive layers from the upper portion of the lobes, the general appearance was anæmic. At the level of the upper border of the corpus callosum, extending very near to it at its posterior extremity, and in the substance of the brain, was found on each side a gummy tumor, almond shaped, with the point outward. The one on the right side was a little larger, and situated a little farther backward than that on the left. The larger was one and one-fourth inch by three-fourths inch and about half an inch in thickness. In each the tumor did not quite fill the cavity, the shrinkage doubtless occurring post-mortem. The growth consisted of a stroma, quite vascular, inclosing soft, gummy, or gelatinous material. There was nothing distinctive in the stroma or its contents that could be made clearer on microscopical examination. In many of its features this case is very like that of W. S. S., reported by Dr. Otis in his work on 'Syphilis and Genito-Urinary Diseases,' though in that case the diagnosis was not confirmed by an autopsy."

A FAMILY EPIDEMIC OF TYPHOID FEVER.

Dr. A. D. Bundy, of St. Ansar, Ia., writes: "Until this winter no case of typhoid fever has fallen under my care, nor do I know of any cases in the county in the past ten or twelve years. During November last a lady, the mother of a large family, contracted typhoid fever while nursing a daughter who lived in an adjoining State, nearly a hundred miles away. The daughter recovered, and the mother returned to her home, bringing an infant of her daughter's, which was about six months old. The baby had been somewhat ill, and was so still, having diarrhœa and fever at that time. The members of the family into which the baby was brought were father and mother, and seven children; four were girls and three were boys. One son, a young man, was a clerk in a store in an adjoining village, and came home only on Sundays, and remained but a few hours at such times. Some two weeks after the baby's arrival a boy, aged seven, was seized with the fever. He had all the characteristic symptoms of the disease, which continued twenty-one days. Next the mother, who brought the baby, came down; she was sick nearly twenty-one days, but had no abdominal symptoms. Next, a son, a young man living at home, was attacked by the disease a few days after the mother, and both of them during the last week of the fever of the boy first mentioned. The next one to be attacked was a daughter, aged sixteen, who was attending school, but who had been home occasionally during the sickness of the first boy. She at first had a pneumonia, clear and distinct, with superadded symptoms, of fever. The last one to be attacked was the young man who was home on Sundays only, whom I have already mentioned. He came down with the disease a few days after the daughter last mentioned. The first fourteen

days went on all well; abdominal symptoms not severe, and temperature not ranging over 104 3° at any time, and then only transiently. On the evening of the fourteenth day he had a large, bloody stool, and within six hours two more of less amount, causing the temperature to drop below normal, and leaving him in an exceedingly prostrate condition, where for two days he seemed to vacillate between life and death. Turpentine and laudanum checked the bleeding, and with stimulants and nutrients the patient rallied. For five days his temperature ranged from 100° to 103°. Then it slowly and persistently rose, ranging from 103° to 104 4°, unless antipyrin was given. The bowels remained quiet. On the twenty-ninth day extreme tympanites suddenly occurred, with severe abdominal pain, and five days later the patient died.

"No others of the family have, as yet, shown signs of the disease. In studying these cases it will be noticed that the severest case came to one who was the least, apparently, exposed. Is the profession satisfied entirely as to the mode in which the disease is transmitted—is it contagious or infectious? I have always doubted the contagiousness of the disease, and held to infection by means of intestinal secretions. Evidently we are not, as yet, through with discussing the origin, as well as the treatment, of this disease."

VOMITING OF PREGNANCY—FAILURE OF DILATATION—RELIEF FROM OTHER MEANS.

Dr. G. M. Lewis, of Vernon, N. Y., reports the case of a colored woman, twenty-six years of age, who had had two children and one miscarriage, and was now pregnant for the fourth time. She had suffered considerably from morning sickness during the early months of all her pregnancies, but beginning at the eighth week of the last pregnancy nausea and vomiting of the most distressing character gave constant trouble. Dr. Lewis began with the administration of mild remedies, such as bismuth, oxalate of cerium, effervescing draughts, nux vomica, calumba, etc., but all failed to give any relief. He then suggested the operation of dilatation. The patient was placed in position, and with a steel expanding dilator the cervical canal was carefully but thoroughly dilated to the full extent of the instrument. This gave no relief, and on the third day following the first operation a thorough dilatation with the steel dilator was again performed, after which the operator inserted his index-finger completely into the cervix. This operation was so thoroughly performed that it was confidently expected that the patient would improve immediately, but the vomiting persisted. Three weeks had now elapsed and she was becoming terribly emaciated; was suffering from hunger, yet unable to retain any form of liquid or solid food; had palpitation of the heart badly two or three times daily; was getting nervous and unable to sleep, and her pulse was 140 and very soft.

Dr. H. W. Carpenter, of Oneida, now saw the case in consultation. During the examination made at this visit he readily inserted his index-finger, up to the second joint, into the os. He was of the opinion that an abortion would result fatally, by reason of the debilitated condition of the patient, and it was decided to try large doses of the mild chloride of mercury. Every other night five grains calomel, with two grains of santonine, were administered, and one-fourth grain morphine was injected hypodermatically. Hypodermatic injections of morphine had been given previously, in order to relieve the palpitations as they occurred; but as they secured to the patient a better night's rest, they were given every night at 9 P.M. for twenty-two nights. Rectal injections of strong beef-tea (acidulated and peptonized) were given twice daily for the first week, after which the patient was able to retain broths on the stomach, and from that date continued to improve. She is now in the fifth month, well and hearty. Dr. Lewis believes the dilating was ineffectual in this case, and that the morphine and mercury did the work.

Progress of Medical Science.

The Relation of the Diseased Nasal Mucous Membrane to Asthma.—Dr. Böcker, of Berlin, summarizes his observations as follows: 1. Reflexes can be originated from every part of the nose. 2. The reflex irritation of the mucous membrane is independent of the corpora cavernosa (Hack). 3. The destruction of the corpora cavernosa does not arrest the reflexes. 4. The swelling of the lower turbinated body is physiological. 5. The reflex-arresting-power of large polyps does not exist. 6. Asthma is seldom associated with nasal polyps. 7. Asthma can be originated under certain circumstances by all mucous membranes. 8. Asthma is usually produced by the bronchial mucous membrane. 9. Odors and psychical impressions can produce asthma. 10. Normally, asthma cannot be produced by the nose. 11. Trigeminus-asthma is caused by morbid states of the nervous system. 12. The impossibility of respiring nasally may produce asthma. 13. Asthma occurring from "catching cold" is originated by swelling of the bronchial mucous membrane. 14. Hay-fever asthma is produced by direct irritation of the bronchi. 15. Cavernous tumors, papillary growths, and adenoid vegetations often produce nightmare. 16. Asthma often is independent of nasal conditions. 17. The treatment of nasal affections can sometimes cure asthma. 18. Extended galvano-caustic operations on the nose are to be avoided. 19. Radical cure of asthma is seldom effected by mere removal of nasal polyps. 20. In the treatment of asthma, constitutional treatment is of the greatest importance.—*The Journal of Laryngology and Rhinology*, January, 1887.

Sulpho-Carbonated Water in Diarrhœa.—Dr. P. de Champeaux relates, in the *Bulletin Général de Thérapeutique* of November 15, 1886, two cases of chronic diarrhœa of very severe type in which most happy results were obtained by the use of sulpho-carbonated water, as recommended by M. Dujardin-Beaumetz. This water is made by adding six drachms of pure sulphide of carbon and thirty drops of essence of mint to one pint of water, shaking thoroughly and then allowing to settle. The water only is used, and the sediment of sulphide of carbon is allowed to remain, but water can be again added to it to be charged as in the first instance. The dose is from one to four tablespoonfuls or more a day in milk. The special indication for the employment of sulpho-carbonated water in chronic diarrhœa is the presence of fetid stools, for the author says that he has tried it in other cases in which the intestinal discharges had no bad odor and has seen no benefit follow its use. It should not be given alone, but only as an adjuvant to other remedies of acknowledged utility in the treatment of chronic diarrhœa. The good effects of the remedy may not be apparent immediately, but within three or four days the stools will begin to lose their fetid character. The sulpho-carbonated water should be continued for a certain time after the desired results have been obtained, as, if abandoned too soon, the fetid stools are liable to reappear.

Bronchitis in Reference to Position during Sleep.—Dr. Nosovitch has examined 738 Russian soldiers, and found bronchitis in 235 (31.8 per cent.). In 97 (13.1 per cent. of the whole number examined, and 41 per cent. of the bronchitic men) the disease was left-sided; in 72 (9.7 per cent., respectively, 30.5 per cent.) right-sided; and in 66 (8.9 per cent., respectively, 28 per cent.) both sided (*London Medical Record*, February 15, 1887). Being struck with such an extraordinary frequency of one-sided localization of the disease ($41 + 30.5 = 71.5$ per cent.) he began to search for an explanation of the fact, and soon came to the conclusion that it might depend upon the habit of sleeping on one side (on the right in some, on the left in others), which habit might involve

a certain difference in conditions with regard to ventilation between the right and left lung. To verify that supposition, he undertook observations for ten successive nights on 612 sleeping soldiers, and found that 37.44 per cent. of them slept on the right side, 33.17 per cent. on the left, 23.09 per cent. on the back, and 6.29 per cent. on the belly. The figures obtained obviously could not support the original hypothesis: for if a defective ventilation of the lung could be a predisposing cause of bronchitis on the same side, a right-sided affection should be met more frequently than the left-sided one, which was not the case. Still the author is inclined to think that there exists a certain etiological connection between one-sided bronchitis and one-sided posture during sleep. When a man sleeps on one side, his respiratory tracts on the opposite (upper) side are more exposed to the action of cold. A certain parallelism of the author's figures seems to speak in favor of that supposition: there were 33.1 per cent. of left-sided sleepers, and 30.5 per cent. of right-sided bronchitis; 37.4 per cent. of right-sided sleepers, and 41 per cent. of left-sided bronchitis; while the number of both-sided bronchitis (28 per cent.) coincides with the number of men who slept on the belly or back (29.8 per cent.), and in whom, therefore, both of the lungs stood under identical conditions in regard to their liability to catching cold. A certain predisposing influence may be ascribed also to the fact that the free (non-compressed, upper) lung of the sleeper makes more extensive excursions, works more, and rests less, than its compeer. Finally, more extensive and free movements of the non-compressed lung may favor a relatively easier and more extensive penetration of "pathogenic principles" into the latter.

Tuberculosis from Circumcision.—Dr. E. Lehmann reports ten cases of tuberculosis in Jewish children, occurring by inoculation during circumcision. The rabbi who performed the operation was the subject of pulmonary phthisis, and it was supposed that the virus was conveyed from his mouth when he applied his lips to the wound to arrest the hemorrhage. In each of the infants, about ten days after the circumcision, the preputial wound became ulcerated and the inguinal glands became swollen and indurated. Syphilis was excluded by the absence of any secondary symptoms. Two of the children died of tubercular meningitis, and three had multiple abscesses and died of exhaustion. Dr. Elsenberg relates a similar case occurring in Warsaw. The preputial wound did not heal, but suppurated, and the inguinal glands became enlarged. Later, an abscess appeared over the left mastoid process. There was no eruption on the skin, and anti-syphilitic treatment gave negative results. The child finally died, and microscopical examination of the diseased tissues revealed the tubercular nature of the affection. The author has met with three additional cases of a like nature.—*Lo Sperimentale*, October, 1886.

Hæmoglobinæmia.—Dr. Silbermann, having carefully studied this subject, formulates the following conclusions: 1. Hæmoglobinæmia and hæmoglobinuria represent a process in which the white blood-corpuscles, as well as the red, are concerned. 2. The hæmoglobin which has been dissolved in the blood destroys the white blood-cells, and thus occasions a decided increase in the amount of fibrin-ferment. 3. This increase of the ferment can also be produced when the hæmoglobin passing into the blood-plasma produces the substance necessary to the formation of fibrin-ferment by abstracting it from the protoplasm of the white blood-cells, without actually destroying them. 4. If there are large quantities of the ferment developed as a result of the action of hæmoglobin in the blood, fatal thrombosis may occur, or an excessive stasis in the large abdominal veins, leading to a fatal anæmia of the brain. 5. If the action of the hæmoglobin is not so intense, not so much fibrin-ferment is developed, and consequently the abdominal venous stasis is not so great, although it is still considerable. 6. The excretion of hæmoglobin through the kidneys is accomplished chiefly in the convolated tubules. 7. If, however, damage has been done to the glomerular epithelium through the general disturbance of the circulation, hæmoglobin will also be excreted in the Malpighian tufts. 8. The hæmoglobin rings found in the glomeruli partly are formed there, partly are produced by the backing up into them of hæmoglobin out of the convoluted tubules. 9. The convulsions appearing in toxic hæmoglobinæmia are to be considered as anæmic, not as uræmic. 10. The fever attending both toxic and paroxysmal hæmoglobinuria is occasioned by the large amount of fibrin-ferment circulating in the blood.—*Zeitschrift für klinische Medicin.*

The Indications for Nephrectomy.—Dr. P. Wagner, of Leipzig, has published an article dealing with this subject. He says (*London Medical Record*, February 15, 1887) that "the indications for extirpation of the kidney have recently been somewhat restricted. There is now much objection to the removal of a wandering kidney of healthy structure; nephrectomy differs from ovariotomy in this important respect, that the kidney belongs to the class of organs on which depend the proper working and vitality of the organism. In performing nephrectomy the surgeon runs the risks of removing a single organ, or of leaving the fellow kidney either already diseased, or liable to become so sooner or later after the operation. This last result is not unlikely to occur, according to some surgeons, after removal of a calculous or suppurating kidney. Cases have been recorded of death from anuria after nephrectomy, in which the remaining organ, on both macroscopic and microscopic examination, appeared to be normal. It is open to doubt whether, under certain conditions, as in aged and very feeble subjects, the remaining kidney is capable of becoming enlarged to such an extent as to perform the functions of two renal organs. It has been pointed out by Rosenheim that even in the most favorable cases the subject of nephrectomy is never able to perform with the remaining organ the full functions formerly performed by two kidneys. Nephrectomy is urgently indicated in cases in which the renal lesion directly threatens life, as, for instance, in cases of severe injury to the organ and malignant disease. That the results of the operation have been so bad in the latter class of cases is owing to the difficulty of establishing a sure diagnosis before the disease has attained an advanced stage. In cases of non-malignant renal tumor the organ should be removed when of such increased size as to give rise to serious symptoms. The operation is also indicated in tubercular disease affecting but one kidney. This, however, Dr. Wagner points out, is a condition that is rare and very difficult to recognize. In cases of renal calculus and pyonephrosis the surgeon should content himself at first with nephro-lithotomy or nephrotomy. In suppurative affections nephrectomy is indicated if the disease be progressive, has caused emaciation of the patient and hectic fever, and is likely to be associated with general amyloid degeneration. Hydronephrosis and renal cysts, apart from special complication, afford no indications for nephrectomy. Dr. Wagner holds that the extra-peritoneal operation should always be performed if possible. In cases of renal calculus, of pyonephrosis, of tubercular disease of the kindey, and of uretal fistula, he would advocate Simon's lumbar incision. In the removal of a diseased wandering kidney, or of a large renal tumor, it would be found necessary to perform the trans-peritoneal operation. In discussing the value of the different methods that have been proposed for determining the presence or the functional capacity of a fellow kidney, Dr. Wagner states that some of these are too theoretical, some applicable only to the cadaver, others too heroic and dangerous, and most of them far too uncertain to be of any real utility."

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, March 26, 1887.

THE CAUSES OF DISEASE IN IMPURE ICE.

THE great sanitary problems which are presented in the supply of pure drinking-water for large towns are so complex that accurate knowledge concerning them must of necessity accumulate slowly as science advances along the lines of new methods of research. A great deal in this direction has been expected, and much of value has been revealed, as an outcome of the study of bacteria, which within the past four or five years has attracted so much attention.

The biological analysis of water has been established as an almost necessary adjunct to the chemical examination; the relations of certain species of bacteria to several forms of serious disease has been definitely made out, and a very large number of facts elicited regarding the form and life-history of different kinds of germs.

While the danger of the transmission of disease from one person or community to another by impure water has long been recognized, the rôle which ice formed from polluted water may play in the same way has not seemed so certain, on account of the very prevalent notion that water cleans itself in freezing.

Still, the dangers which may lurk in impure ice have not been overlooked by physicians, and several severe outbreaks of disease have with very good reason been attributed to the use of bad ice. But a certain measure of uncertainty has existed even in the most marked cases, owing to the lack of exact knowledge regarding the purifying agency of cold. For this reason medical men have, as a rule, been disposed to caution in condemning suspected ice.

It appears, if we may accept the conclusions of workers in bacteriology, that the greatest danger from water, as well as ice, lies not in the things which can be appreciated by sight or taste, but in those invisible foes of man, the bacteria which may cause disease.

Our neighbors at Albany have for a long time been agitated over the propriety of pumping up the Hudson River water which is contaminated with Troy sewage and using it unfiltered for potable purposes. New Yorkers have looked on with complacency at this sanitary agitation, their equanimity undisturbed owing to their consciousness of the general excellence of the Croton water system. The unpleasant possibility of a pollution of the Hudson River ice, which we so largely use, from Troy and Albany sewage has not greatly disturbed us, since the bliss of our ignorance has been too comfortable to give up without a reason.

We need not apologize for devoting so large a part of the present issue to a series of studies which throw much light on the subject of impurities in ice in general, and particularly in that which is used in New York. These studies seem to establish, on precise experimental evidence, the fact that disease-producing bacteria may live for a long time in ice. The bearing of this fact alone on the use of ice which is cut in sewage-polluted water anywhere is too obvious to need further comment.

It is very difficult to establish an absolute standard of purity as regards the bacteria, either in water or ice, because as yet so little is known about the hosts of them which seem to be the natural denizens of most water. We would call attention to the fact that Dr. Prudden has endeavored, in laying down his standard of bacterial purity, or rather of allowable bacterial impurity, in water or ice, to place his criterion, even at the expense of absolute definiteness, on the side of safety, a position which would seem to be necessary, so long as our knowledge of common bacteria is incomplete.

While the tendency of these researches would seem, at first sight, to add to the burden of a moderately safe existence, a careful study of the results shows that in reality they are on the whole reassuring rather than otherwise, because in the place of suspected unknown dangers they point out to us the exact nature and extent of the evils, and the easily established measures by which their avoidance may be secured.

MAKING THE DEAF-MUTE HEAR.

HALF a century ago Braid, of England, stated that he had been able to make several congenital deaf-mutes hear by hypnotizing them, and causing them to listen to various sounds. Braid's observations do not seem to have attracted much notice, or at least to have been extensively repeated. Dr. Berkhan, of Braunschweig, however, has recently taken up the matter and made experiments upon nine young persons who were completely deaf.

The deafness was first thoroughly tested by various kinds of noises, the person was then hypnotized and then the hearing tested again. The following account will best show the result: G. S——, aged fourteen, healthy and well grown, from his earliest youth had been deaf and dumb. He was hypnotized. During the hypnosis moderately loud noises near the ear caused quick movements of the head and body. After hypnosis he heard spoken behind his back the sound "a" very plainly; o, not so plainly; the other vowels not at all; knocking on the door, plainly; whistling, not at all; ticking of a clock, not at all. Various tests made during the subsequent year and a half showed that this power to hear certain sounds was not only retained but strengthened. In three other cases similar results were obtained; in five cases the experiments were failures.

It is not claimed that by hypnosis the deaf may be made to hear well, but in a certain proportion of cases it seems possible to put them in slight communication with the external world by means of the sense of hearing.

To the man who has heard nothing for years the screech of a locomotive may sound sweeter than the symphonies of Beethoven.

COLLECTIVE INVESTIGATION REGARDING CHOREA.

The report of the Collective Investigation Committee of the British Medical Association upon the subject of chorea has been published. It is based upon 439 cases, and the facts are carefully collated by Dr. Stephen Mackenzie. The report is an interesting one, yet we confess to have found in it no new facts that will change present views upon the history of the disease. As to the mooted point of its relation to rheumatism, it is stated that that disease preceded the chorea in about twenty-six per cent. of cases, which is only a little in excess of the figures of Dr. Sturges (twenty per cent.). Scarlet fever preceded it in twenty-nine per cent.; anæmia in twenty per cent.; mental overwork in sixteen per cent.; and some form of nervous shock in fifty per cent. The usual duration was from two to three months. The death-rate was two per cent. Some cardiac lesion was present in thirty-two per cent. of cases, in one-half of which rheumatism was present.

A large number of complications of the most varied character were noted, the most common one being headache. Nervous affections of some kind were noted in forty-six per cent. of the families of those affected, "nervousness" being most common, and next it chorea. Arsenic, iron, and full feeding, with rest, were the main things relied upon in treatment.

THE ACADEMY OF MEDICINE.

The Academy of Medicine may justly be regarded as the present and future centre of medical interest in this city. It holds and will maintain this position, not only by its age, but far more largely by the gradual accumulation of those material conditions which most influence the profession, and give permanency to its character and reputation. The first and most important step which the Academy took in advance was the purchase of a suitable building. This act gave what it sadly required—a local habitation and a name. Then followed the erection of an audience and library room, which have naturally proved very attractive features of its equipment. The rapid growth of the library, now scarcely second in value to any other in the country, and the presence on its tables of all the medical journals of the world, complete the appointments which place the Academy on the basis of the great central medical organization of the city. Of the future of the Academy we may safely predict that, with judicious management, it will at no distant day be the most powerful and influential scientific and professional corporation in this city. The munificent sums of money which have fallen to it during the past year are only precursors of larger endowments which it will receive in the future. In view of the growth of the Academy, and its prospectively commanding position among the institutions of the city, it is pertinent to inquire as to the conditions essential to the fulfilment of its great mission.

Its location must be more central. Looking forward to the future distribution of the profession in and around New York, and the direction and extension of lines of rapid transit, it is evident that some more central and accessible location should be selected.

The Academy should have a building commensurate with the present and future wants of the profession. In addition to its assembly hall, and library hall with its rooms for private study, there should be parlors for receptions, lodgings, and café for medical men visiting the city, a museum with all of its appointments, and laboratories for special investigations.

The internal organization of the Academy needs reconstruction. Its business should be transacted at quarterly meetings held for that special purpose, thus saving valuable time now lost at the regular meetings. The scientific meetings should be entirely devoted to the discussion of vital and current questions in the several branches of the medical sciences, selected by a competent scientific business committee. The subject to be discussed should be so stated as to sharply define the question at issue, and every speaker should be required to conform rigidly to parliamentary rules. The Academy would thus become the great theatre of contention where the best talents and attainments of the profession would be brought into honorable and earnest effort in the elucidation of scientific truths. There is, in the profession in New York, a class of young men who would develop high forensic abilities if there was a forum where they could be trained to the proper exercise of their natural and acquired powers. The sessions of the Academy would also become of far greater importance to the profession at large were they thus devoted to disputations on subjects of immediate interest by members who, thoroughly prepared for the discussion, delivered their arguments in set forms of speech. The sections should be devoted to the reading of papers and the discussions of the topics which they present, but no paper should be read at the meetings of the Academy except as a part of the discussion of the specific topic under consideration. While the sections would thus become the active and efficient auxiliaries in the selection and preparation of the scientific business of the Academy, they would be most interesting societies in all branches of the medical sciences.

One more feature should be added to the scientific work of the Academy, viz., courses of lectures on special subjects. There could be three or four courses of lectures annually, which would prove most attractive and instructive to the great body of medical men.

These are but a few of the many suggestions of reform which occur to us in considering the future of the Academy. They are put forth as suggestions merely, but we trust they will awaken a new interest in our great central medical body, and lead to mature plans for its advancement to a higher and more influential position.

KREMJANSKI ON THE TREATMENT OF PHTHISIS BY ANILIN OIL.

The most striking communication made at the Congress of Russian Physicians in Moscow, in January last, was by Professor Kremjanski, of Charkow. The title of his paper was, "The Treatment of Phthisis on the Basis of its Parasitic Origin." Professor Kremjanski accepted the theory of the bacillary origin of phthisis, and de-

scribed a mode of treatment based on this view, whose results, if true, have been rightly characterized as "astounding" and "revolutionary." We are unable to give a detailed account of his method, as only a synopsis (in the *St. Peterburger Medicinische Wochenschrift*) is as yet accessible.

Professor Kremjanski attacks the bacilli with a diet peculiarly innutritious for these organisms, and with germicidal drugs given internally and externally. The principle and peculiar feature of the diet is an abundance of acid-bearing substances, such as "kwass," lemonade, acid fruits, kumyss, and kefir. Internally he gives salicylate of soda, benzoate of soda, besides causing the patients to breathe an atmosphere containing ethereal oils. As the specific for disinfecting the lungs and blood in phthisis he gives inhalations of anilin oil by means of a specially constructed atomizer. The reader of the paper presented two cases illustrating his mode of treatment. One of these had been given four drops of anilin daily, with tincture of menthæ and ipecac, acid diet, with raw flesh, and inhalations of anilin.

Considerable skepticism was expressed regarding Kremjanski's results, and a commission of five was reported to inquire into them. Professor Kremjanski is sure that the investigation will be for him a triumph.

NEW YORK DUST AND THE DISORDERS OF SPRING.

THE month of March in New York City is the most comprehensively and penetratingly dirty month out of the whole year of dirty months in this never-overwashed city. Dr. Morell Mackenzie thinks American catarrhs are largely due to the dust, and it is not unreasonable to believe that the tremendous clouds of unsterilized earth which are driven into the faces of our city's population during this season have something to do with the excess of coughs and colds and the high mortality-rate during this period, which in some years is exceeded only in the hot months of summer. It is not so much spring-medicines, "one hundred doses for a dollar," as cleaner streets that New Yorkers need.

THE EASTERN DISPENSARY.

WE take pleasure in chronicling the fact that the Eastern Dispensary has been added to the list of the institutions which pay their attending physicians. There does not seem to be any good reason why medical men alone, of all professional classes, should work without recompense. And we regard it as a step forward in the status of our profession when dispensary directors begin to see that it is wise and just to pay their medical officers for services rendered.

"REPUTABLE" AND "REGULAR."

WE venture to say that most classes of intelligent people would prefer to be considered "reputable" rather than "regular" in the eyes of their fellow-men. Regularity is an excellent thing, no doubt, especially in the matter of the bowels, but a man's reputation is or ought to be the dearest thing to him in life. We make these remarks *à propos* of the organization of a new medical society in Cincinnati, when a lively discussion ensued over a proposition to have the membership consist of "reputable" physicians instead of "regular" physicians.

Some stump-speech logic was indulged in over the subjec tof irregulars, and the motion to substitute "reputable" for "regular" was lost by a large majority. Henceforth, the Hamilton County Medical Society may not have any reputable members, but they will all be regular. We trust that some good fortune may bring it about that all its "regulars" will be reputable. We know of some who are not.

But is it not true that a reputable physician cannot be an irregular one?

BENZOYLTROPIN, A NEW LOCAL ANÆSTHETIC.

MANY efforts have been made to find some agent equal in local anæsthetic effect to cocaine. The kawa-kawa of Lewin, obtained from *Piper methysticum*, was found to have some such property, but to be far inferior in practical value. Apomorphia has also some local anæsthetic power if used in colossal dosage. Recently drumine has excited attention, but trials of it in England have given unsatisfactory results.

Professor Wilhelm Filehne, of Breslau, has been investigating the subject from a chemical stand-point, and while he has not yet obtained, synthetically, cocaine or a substitute for it, he has found in what direction to look, and also the principle in the cocaine molecule which gives to it its local anæsthetic action. Filehne discovered that the union of tropin, a molecule derived from atropin, with benzoic acid produced a substance which he calls *benzoyltropin*. This possesses "an exquisite local anæsthetic effect." It has also the mydriatic power of all the tropeïnes; paralyzing accommodation in the same way.

The ecgonin molecule in cocaine plays an indifferent rôle, according to Filehne, and the benzoyl molecule is the active one. Some anæsthetic action was found to exist in a large series of benzoyl derivatives which were experimented with. The most active, after the benzoyltropin above referred to, was benzoylmethyltriacetonalkamin. None of the series could be used practically because they caused, at first, burning and painful sensations, applied to the conjunctiva.

The benzoyltropin is, therefore, the nearest approach to cocaine in practical utility. The objection to it is its mydriatic power and its higher cost.

SUPERFECUNDATION.—Dr. J. B. W. Nowlin adds to the list of cases of superfecundation (*The Southern Practitioner*). In 1863 he was called to see a negro woman who was in labor. When he arrived, he found that she had given birth to twins. One of them was a pure African, with all the typical features of that race, and the other a very bright mulatto, exhibiting evident characteristics of the Caucasian race. The mother was a pure black, with all the typical features of the African, as was also the husband. Upon inquiry Dr. Nowlin ascertained from the mother that she had permitted intercourse with a white man living with her master the day succeeding the same act with her husband. There were two separate placentæ and cords.

News of the Week.

Another Sure Cure for Colds.—Dr. J. H. Whelan (*The Practitioner*), after truthfully demonstrating the inefficiency of all present methods of treating colds, recommends as very nearly specific the following:

℞. Quininæ sulphatis ..... gr. xviij.
Liquoris arsenicalis ..... ♏ xij.
Liquoris atropinæ ..... ♏ j.
Extracti gentianæ ..... gr. xx.
Pulveris gummi acaciæ, q. s. ut fiant pilulæ xij.

Sig.—One every three, four, or six hours, according to circumstances.

He adds: "If these pills be commenced in the early stage of a common cold, *i.e.*, when the affection is as yet confined to the nose and pharynx, the affection will be nipped in the bud. At starting one pill should be taken every three or four hours, and later on every six. If a catarrhal subject has a box of these pills always at hand, he has, I believe, a weapon wherewith to meet and defeat his enemy. The longest time I have seen a cold last while the patient was fairly taking these pills was three days."

We Regret to Learn that the well-known surgeon Dr. William Hunt, of Philadelphia, was recently run over by a wagon and had his right arm broken.

Dr. H. C. Wood, of Philadelphia, has been offered the chair of medicine at the Johns Hopkins University.

The Prescribing of fluid ext. rham. cat. to a sensitive spinster caused a Philadelphia surgeon to lose his patient.

Memorial to Dr. Ambler.—The bronze tablet recently executed from funds provided for the purpose by the medical corps of the United States Navy has just been hung in the Corcoran Art Gallery, Washington, on exhibition. Eventually the tablet will be placed in the Surgeon-General's office at Washington. The memorial is in honor of Dr. James Markham Ambler, the surgeon of the Jeannette Exploring Expedition to the Arctic regions. The inscription reads as follows: "James Markham Ambler, M.D., U. S. N., Lena Delta, October 9, 1881. Duty stronger than love of life."

Sixteen Medical Colleges in Ohio.—*The Columbus Medical Journal* has discovered a new medical college at Lebanon, O., making sixteen in all that the fortunate State of Ohio now possesses. The Lebanon College has always had a faculty that outnumbered the class.

A United States Government Commission to Investigate Yellow Fever Inoculation.—The Sundry Civil Appropriation Bill passed by the last Congress provides an expenditure of a sum not exceeding $10,000 for the investigation of methods practised in Mexico and Brazil for preventing yellow fever by inoculation. The President is authorized to cause the expenditure to be made, and may appoint any person to carry it out.

Quinine is now selling at about fifty-two cents per ounce.

Dr. John Marshall Paul, a prominent physician of Belvidere, N. J., died suddenly on March 17th, of pneumonia. He graduated from Williams College in 1864, and then served six months in the Medical Department of the Sanitary Commission of the Army of the Potomac. In 1868 he was graduated from the University of Philadelphia, and served a term as resident physician in St. Mary's Hospital, Philadelphia. In 1869 he moved to Belvidere, where he had since practised.

Is Pneumonia Contagious?—Under this title, *The Sanitary News* says that at a house in Providence, R. I., about a month ago, a lady died of pneumonia. A week later, two more fatal cases developed in the same house. The man who was sick was an Odd-Fellow. He was cared for by a brother of the order and a physician, both of whom are now seriously sick with the disease. The physician's name is Dr. Lester S. Hill. Similar cases to these have been reported before.

A State Board of Health for Vermont.—A State Board of Health has just been established in Vermont, the twenty-ninth State in the Union to be provided with such an organization.

The Philadelphia County Medical Society has memorialized the Legislature in opposition to the passage of Section 10 of the proposed Pharmacy Law, now pending. This section so far repeals the Registration Act as to permit druggists to engage in the practice of medicine, provided that they conduct only an office practice. The Society urges that this proposition is unworthy of approval and support, for many reasons, but above all because of the danger to which it exposes the lives of individuals and the health of the community. The Druggists' Association of Philadelphia has also taken similar action.

The College of Physicians and Surgeons of Chicago held its Commencement exercises on February 21st, when fifty-three gentlemen received their degrees.

The Central College of Physicians and Surgeons of Indianapolis, Ind., conferred degrees upon four graduates at its Commencement, February 26th.

The Minnesota Hospital College held its sixth Annual Commencement on March 11th, and conferred degrees upon twenty graduates.

The Louisville Medical College held its Commencement exercises on February 25th, with sixty-three graduates.

The Memphis Hospital Medical College held its seventh Annual Commencement on March 1st, and graduated a class of forty-one.

The College of Physicians and Surgeons of Baltimore held its fifteenth Annual Commencement on March 15th, and graduated a class of eighty-eight.

The Medical College of Ohio held its eleventh Annual Commencement on March 8th, and graduated eighty-four students.

Miami Medical College held its Annual Commencement on March 9th, when a class of twenty-nine was graduated.

The Baltimore Medical College held its seventh Annual Commencement on March 15th. Degrees were conferred on eight graduates.

Medical Colleges at Odds.—The Legislature of Ohio has been appealed to by the Medical College of Ohio, and requested to pass a bill granting to it also the privileges of the county hospital in proportion to the number of students in attendance. The Miami Medical College now has the exclusive privilege of using this hospital.

It is Rumored that Dr. Lange, of this city, has resigned his hospital appointments here and gone to Germany, to accept an official position under the German Government.

Gastric Hysteria.—A Saginaw, Mich., daily reports in detail the case of a girl, seven years of age, who for seven weeks has practically taken no food. She has no organic disease, it is said, and has been reduced by her fast to such a condition of weakness and emaciation that death is expected.

Christian Scientists can Practise Medicine in Iowa.—In a recent test case brought to trial by Charles E. Kelly, a "Christian Scientist," at Mason City, Ia., before a justice of the peace, the jury rendered a verdict in favor of the defendant. A man practising the electric bath business in Mason City also proposes to test the constitutionality of the law.

The Mortality-rate of Diphtheria in Berlin.—In 1886 there were 6,649 cases, with 1,535 deaths, giving a mortality-rate of 23.1 per cent.

An Immense Hospital, to contain six hundred and sixty-four beds, is to be built at Madrid. There will be ten pavilions, constructed on the Tollet system.

Immediate Perineorrhaphy.—Dr. M. J. Madigan, of Brooklyn (*Medical Standard*), denies the value or propriety of immediate perineorrhaphy after parturition. He cites some authorities who have admitted that good results were often not obtained, and concludes by saying: "The principles laid down by Billroth are sufficient to demonstrate that, pathologically, the position of the gynecologist as to immediate perineorrhaphy is invalid. Whenever a laceration occurs in my practice, I place the patient on her side, bring the knees together, secure apposition by means of pads, placing absorbent cotton over the laceration, and wash the parts with an antiseptic, alcoholized, aqueous solution. The results are excellent. If perineorrhaphy be needed, it can be much more easily performed, with better chances of success and less discomfort to the patient, two months after delivery than during the lying-in period. It must be admitted that here, as elsewhere, the teachings of gynecology have led the practitioner to look upon woman as an appendage of her genito-urinary organs, and have taught him to disregard the most ordinary principles of general pathology."

A German Hospital in Brooklyn.—The sum of $50,000 has been promised to form part of a fund for erecting a German hospital in Brooklyn.

The Meharry Medical College, on Febrnary 21st, conferred degrees upon ten gentlemen of color.

A Medical Palace—A Joy Forever.—Under these titles the local paper at Cleveland, O., refers to the new college building of the Medical Department of Western Reserve University. This has recently been erected through the liberality of one of Cleveland's business men, Mr. John L. Woods, at a cost of $175,000. The building is certainly a beautiful one architecturally, and thoroughly equipped in every way. The college is fortunate in having received the gift of the land from Senator Payne, and a fund of $10,000 from Mr. H. B. Hurlbut for establishing a dispensary.

The Michigan State Board of Health is one of the oldest and most efficient organizations of the kind in the country. Its annual reports have often contained articles of the greatest practical value, and through the labors of members, and especially of its efficient executive officer, Dr. Baker, saving of life and money have been accomplished. Yet, at almost every session of the Legislature during the fifteen years' existence of the Board a bill has been introduced to abolish it. The Board is not enough of a political institution, apparently, to suit some Michiganese statesmen.

The Emperor William's Physician, Dr. Lauer, has been presented with the sum of 300,000 marks, with a statement recognizing his efficient services.

Memorial Tablet to the Late Dr. Austin Flint.—The Commissioners of Charities and Correction have had executed a tablet to the memory of Dr. Flint, to be placed in Bellevue Hospital. The tablet is unique in design and exquisite in workmanship. The inscription which is imprinted on the shining brass, in Roman letters of black enamel with initials in red enamel, is surrounded by a band of conventional palm-leaves, relieved at intervals with mat scroll-work. The inscription reads as follows: "In Memory of Austin Flint, M.D., LL.D. Entering the profession with broad culture and thorough education he remained an active physician to the last day of his life. As a medical writer he added to the knowledge of the American profession and to medical science. As a teacher he was loved and respected by thousands of his pupils in all parts of the country. As physician to Bellevue Hospital for twenty-five years, he contributed largely to its reputation by his character, acquirements, labors, and wise counsels. Erected by the Commissioners of Public Charities and Correction. H. H. Potter, President; Thomas S. Brennan, Charles E. Simmons."

Changes in Army Hospital Stewards.—We learn that Surgeon-General Moore is taking active steps to carry out the provisions of the recent act of Congress affecting the corps of hospital stewards of the army. It is proposed that the name of these attachés of the army be changed to apothecaries.

Schroeder's Successor.—It is believed that Professor Winckel, of Munich, will succeed the late Professor Carl Schroeder as Professor of Obstetrics at Berlin.

Four Bills for Regulating the Practice of Medicine are now before the State Legislature of Kentucky. This looks as though the profession of the State was failing in the duty of carefully looking after its own interests and those of the public.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, February 9, 1887.

T. Mitchell Prudden, M.D., President, in the Chair.

Dr. G. C. Freeborn demonstrated under the microscope the results of

TWO NEW METHODS OF STAINING ELASTIC FIBRES,

namely, Lustgarten's and Herxheimer's. Lustgarten (*Fortsch. d. Med.*, iv., 1886, No. 22, p. 734) employs for this purpose Victoria blue, a basic aniline dye, from the Baden Soda and Aniline Manufacturing Company.

Sections of tissue hardened in alcohol do not give satisfactory results, but fresh tissue hardened in Flemming's solution for twenty-four hours and then further hardened in alcohol gives sharp pictures.

Sections of tissue, hardened as above, are placed in a mixture of one part of a concentrated alcoholic solution of Victoria blue and four parts of water for twenty-four hours. The sections are then removed from the staining fluid, washed quickly in alcohol (five to ten seconds), drained of the superfluous fluid by placing them on a bit of filter paper for a few seconds, cleared in oil of bergamot, and mounted in Canada balsam.

Connective tissue and cells stain a faint green, nuclei a darker green, elastic fibres a light green, but darker than the other elements. In the specimens under the microscopes he had not succeeded in obtaining the exact shades described by the author. In his specimens the tint was bluish. This difference in color might be due to the grade of the dye employed, as he had found that the Baden Company manufacture three different shades. The dye used by him is known as the medium shade.

Herxheimer (*Fortsch. d. Med.*, iv., 1886, No. 24, p. 785) hardens fresh tissue in Müller's fluid, though good pictures may be obtained with tissues hardened in alcohol, picric acid, or Flemming's solution.

As a staining solution he uses the following mixture: 1 c.c. of hæmatoxylin (best obtained from Grübler in Leipsic), 20 c.c. of absolute alcohol, 20 c.c. of water, 1 c.c. of a saturated solution of lithium carbonate in water. Alum solutions of hæmatoxylin, Heidenhain's solution, or Weigert's solution may be used. The specimens shown were stained with Weigert's solution.

The sections, which should not be over 2 to 100 mm. thick, are placed in the staining solution for from three to five minutes. They are then removed and placed directly in a dish of the officinal solution of the chloride of iron for from five to twenty seconds. In this solution an iron lake is formed with the hæmatoxylin, and immediately afterward the decolorization takes place. Too prolonged action of the iron solution will remove the color from the finest fibres. After removing the sections from the iron solution, they are well washed in a large dish of water, when clouds of color will be given off from the sections. Then pass through alcohol twice, clear in oil of cloves, and mount in Canada balsam. The iron solution and the alcohol should be frequently renewed.

The elastic fibres stain a blue-black to a deep black color, and stand out sharp against the underlying connective tissue, which is stained more or less of a light gray, often running off into a bluish tint. Nuclei sometimes stain of a grayish tint.

VERTEBRAL CARIES—LAST CERVICAL AND FIRST SIX DORSAL—PARAPLEGIA—RECOVERY OF PARAPLEGIA—ENLARGEMENT OF RIGHT HEART—HEMORRHAGIC INFARCTION OF LUNGS—DEATH.

Dr. John F. Ridlon presented the spinal cord of a patient who died in St. Luke's Hospital on the 7th inst.

The history was as follows: Mary D——, six years of age, was admitted October 24, 1883, to the orthopædic service under the care of Dr. Newton M. Shaffer and himself. Both parents died of consumption. She had three healthy brothers, and two brothers died from causes unknown. She had four healthy sisters. Other hereditary history not known. The curve in upper dorsal spine was first noticed in January, 1881—six years ago. From that time the curve gradually increased in spite of treatment by a brace at one of the public institutions in this city for the treatment of cripples. On her admission to St. Luke's Hospital, three years and three months ago, her general condition was fairly good. There was a large kyphosis which involved the four first dorsal vertebræ. There was paraplegia to the following degree: She could not stand alone; there was very little voluntary motion in the lower extremities; and all the tendon reflexes of the lower extremities were greatly exaggerated. Sensation seemed normal. No bladder or rectal symptoms.

From that time, October 24, 1883, to June 29, 1885, there was no treatment except rest in bed. Meantime the paralysis of the lower extremities was complete—there was not the slightest control over a single muscle. From this time on, the same conservative treatment being pursued, there was a gradual and steady gain. On March 10, 1886, she was able to move the toes somewhat, flex the feet to a degree, and flex the legs on the thighs. On April 6th she walked about forty feet. Reflexes were reduced almost to normal. On April 14th Taylor's antero-posterior spinal support and chin-piece with Shaffer's ball-pivot joint was applied and the patient was allowed up. On April 16th, after being up two days, she seemed so unsteady on her feet that she was again put in bed, the brace being kept on without the chin-piece. On October 20th she was again allowed up for five minutes twice a day. December 1st she was able to walk alone the length of the ward and back. There was a slight exaggeration of the tendon-reflexes in the lower extremities. December 22d, allowed up half an hour twice daily. January 27, 1887, began to have difficulty in breathing. She was under the care of Dr. A. B. Ball till February 1st, and of Dr. F. P. Kinnicutt from that time till her death, at 3 A.M., February 8th.

Post-mortem examination by Dr. Frank Ferguson, February 8, 1887. Body emaciated. Rigor mortis slightly marked. Spinal curvature and projection forward of the breast. Diaphragm at the sixth rib on either side. Loose old adhesions generally distributed over both lungs. Tubercles at apex of left lung. Areas of hemorrhages of small size. Mucus and pus in the bronchial tubes. Old phthisis at apex of right lung. Numerous hemorrhages (infarctions) of considerable size in lower lobe of right lung. Heart was larger than normal. Left ventricle moderately dilated; its walls thin; its valves normal. Right ventricle enormously dilated; its walls thin; its valves normal; its muscular tissue showed fatty degeneration. Spleen normal in size, firm in consistency, dark in color; kidneys congested, firm in consistency, capsule not adherent, surface smooth, markings distinct. Both organs were alike. Mesenteric glands moderately increased in size. Stomach, pancreas, and gall-bladder normal. Liver: Peripheri of acini were anæmic and fatty. Urinary bladder normal. Caries of the spinal column involving the last—seventh—cervical and first five dorsal vertebræ. The angle of the curve was very sharp (so that the upper surface of the sixth dorsal and the under surface of the sixth cervical were not more than an inch and a half apart, and this space was filled in with a cheesy mass from the cord forward, there being but a thin shell of bone anteriorly). The cord was about half an inch in diameter, flat, and its gray substance was not distinguishable. Above and below the angle the spinal cord seemed normal.

[The specimen was referred to the Committee on Microscopy.]

Remarks.—Dr. Ridlon said that it was difficult to tell

at the beginning whether recovery from the paraplegia attending Pott's disease would occur within two months or three years, and he knew of no method of treatment which would enable one to answer this question. Is there any treatment more satisfactory than rest in bed and the support given by a fairly good fixation apparatus? He had used iodide of potassium, and had become convinced that it produces no effect upon the paraplegia, unless there be reason to believe that hereditary syphilis is present.

To the naked eye the gray matter in the specimen presented was apparently destroyed, but whether or not the nerve-fibres had been destroyed he was unable to say.

He would also ask if anyone had seen a case in which paraplegia was present and the kyphosis was in any other region than the upper dorsal.

Again, were we to expect dilatation of the right side of the heart as the result, in these cases, which would give rise to a pulmonary condition that would terminate life?

Dr. Van Santvoord referred to a case which he treated with the actual cautery, while an interne in Bellevue Hospital. The cautery was applied to relieve pain, but the paraplegia began to disappear at once, and after a time the girl recovered from the paralysis.

Dr. Ira Van Gieson remarked concerning restoration of function after destruction of nerve-tracts that a recent observer had experimented under Stricker's direction by removing a portion of the motor tract in dogs, and had found that function was restored in from three to six weeks. The conclusion was that the restoration of function occurred through collateral channels in the motor tracts injured or destroyed.

Dr. H. J. Boldt presented a specimen of

PERSISTENT BRONCHO-PNEUMONIA

removed from the body of a child nine months old that died with symptoms of meningitis. There had been nothing to direct attention to the chest, and the child had been healthy until the development of the meningitis.

The lower portion of the left lung was adherent to the chest-wall and had one cavity filled with pus. All the other organs were healthy, except the brain, which showed simple meningitis.

METRITIS—PERIMETRITIS—ENLARGED GLANDS.

Dr. Boldt presented the pelvic organs removed from the body of a woman, forty-nine years of age, who came under his observation on October 1st, last, when she claimed that she had enjoyed good health until a few months previously. About one year ago a small tumor was detected in the right inguinal region, which was regarded as an ovarian cyst. When Dr. Boldt first saw her the tumor had reached considerable size, and he advised an operation, but it was declined, and the patient died of exhaustion.

At the autopsy the uterus was found enlarged, its walls thickened, and the entrances to the Fallopian tubes were obliterated. On the right side there was a cyst that had been bound down by adhesions, and upon the top of it the tube could be distinctly traced. On the left side it was impossible to determine, positively, by gross examination, the presence of either the tube or ovary. The retroperitoneal glands were enlarged, and it was thought that they might be sarcomatous.

The case illustrated the importance of early operation for removal of ovarian cyst.

The specimen was referred to the Committee on Microscopy.

Dr. W. H. Porter presented a pair of lungs which illustrated

ACUTE ANTHRACOTIC PNEUMONIA

in connection with acute lobar pneumonia. He had seen four or five such cases, all occurring in workmen on the new aqueduct. The symptoms had been chill followed by moderate rise of temperature and continuation of febrile movement for a few days, and finally the symptoms all abated and the patients were about the wards of the hospital in a very comfortable condition, but died suddenly on the development of dyspnœa and pulmonary œdema.

The anthracotic part was apparently an acute development of this peculiar lesion. He had seen two or three cases in which this anthracotic condition of the lungs only was found, without evidence of inflammatory exudate into the air-vesicles. Whether or not the anthracosis predisposed to the occurrence of lobar pneumonia, he was unprepared to answer; it might be that these persons had the lobar pneumonia because of the exposure incident to their work.

The President remarked that this was an interesting class of cases, especially in connection with the new notions of the pathology of acute lobar pneumonia. Although the particular bacterium which causes this form of pneumonia has not been established, and it is not improbable that there may be several capable of causing it, the general impression is that there are micro-organisms which bear the relation of cause and effect to this disease; but it also remains that there are predisposing factors which are equally important, and perhaps there is a peculiar exposure that predisposes to acute lobar pneumonia. Here, however, is another cause, apparently, and the acute irritation produced by the little foreign particles may be a predisposing factor. In that respect, especially, the class of cases mentioned by Dr. Porter becomes one of great interest.

Dr. Porter had thought that the acute lobar pneumonia in these cases was the result of the acute anthracosis, without reference to bacilli.

DILATED URETERS.

Dr. J. S. Thacher presented two specimens. The *first* was found at autopsy in the body of a woman. The cause of the dilatation was a collection of small polypoid outgrowths from the mucous membrane in the middle part of the ureter and over a space an inch or an inch and a half long. The dilatation of the pelvis of the kidney was not extreme. The little growths, which were numerous, were not fibroid in character, but rather cystic, containing granular matter and squamous epithelia.

The *second* specimen was from the body of a fœtus six months old, and the ureters were dilated to about the size of the thigh of the embryo at that period. The pelves of the kidneys were slightly dilated. The bladder was enlarged, its walls hypertrophied and quite firmly attached to the anterior wall of the abdomen. He was unable to find any cause for the retention of the urine.

Dr. Ira Van Gieson presented a specimen which showed:

A FOREIGN BODY IN THE EYE—PANOPHTHALMITIS FROM INJURY.

Three weeks before enucleation the patient was struck by a twig, penetrating the sclera about one centimetre posterior to the sclero-corneal junction and passing through the globe to the diagonally opposite ciliary body. The foreign body was thorn-shaped, rather sharply pointed, and measured one and a half centimetres in length.

Microscopical Examination.—The foreign body was surrounded by a zone of granulation tissue. The lens was absent and the collapsed capsule surrounding a small mass of new connective tissue occupied approximately its normal position. Just posterior to the foreign body was the detached retina. Between the detached retina and the optic nerve entrance was a mass of extravasated blood. The anterior chamber was filled with pus. The iris and ciliary body were infiltrated with pus-cells.

Dr. R. Van Santvoord presented a specimen of

POSSIBLE TUBERCULAR DISEASE OF THE PHARYNX

removed from the body of a child eighteen months and nineteen days old. Five months ago it was noticed to be

suffering from irregular attacks of fever, with cough and râles in the chest, and that it was emaciating somewhat. There was some difficulty in swallowing at one time, but nothing special to explain it was found. The child died four days ago. At the autopsy there were found two ulcers, one in each pyramidal pouch, and about an inch in length. There were also ulcers on either side of the external surface of the epiglottis, about one-fourth of an inch wide. On the posterior wall of the pharynx were irregular ulcers, and one small point of ulceration in the left tonsil. The process did not extend into the nose. The bronchial glands were enlarged, but were not cheesy. The upper and the lower lobes of the right lung were solidified largely by broncho-pneumonia, and scattered through the consolidation were yellowish spots, which which were apparantly tubercular nodules that were becoming cheesy. Nothing especially noticeable was found in the abdominal contents.

About fourteen months ago he presented a similar specimen, and in that case difficulty in swallowing was noticed only four days before the death of the child. The lesion had been described as occurring in adults, but whether it was frequent or not in children he was not prepared to say. The specimen was referred to the Committee on Microscopy.

Dr. Ridlon had been led to believe, from clinical observation, that lesions of this character which it had been customary to regard as tubercular occurred without any hereditary history of tubercular disease, but where there was a positive history of syphilis.

Dr. A. P. Dudley presented a specimen of

CANCER OF THE UTERUS

that developed upon the site of an old cervical laceration in a woman forty-eight years of age, who had borne eight children, and had been attended by a midwife. She was not aware that laceration had occurred. The malignant disease was quite far advanced, and was removed by the vaginal operation. Considerable difficulty was experienced in the operation because of the attachment to the uterus of two fibroids, and the mass was finally removed in sections by means of the elastic ligature.

The patient was under the influence of ether nearly three hours. She did fairly well until the following morning, when it was found that there was suppression of urine, and death occurred thirty-eight hours afterward.

Dr. W. H. Porter made the autopsy, and found that the entire peritoneal cavity was absolutely free from suppuration. The kidneys were in a condition of rapidly advancing acute parenchymatous metamorphosis, and the liver was in the same condition, and also cirrhotic. He had seen twelve or thirteen similar cases, in which this acute disease of the kidneys had developed after severe surgical operations, while everything about the site of the operation indicated a reparative process, but the symptoms were those ordinarily ascribed to septicæmia. In these cases the urine contained neither casts nor albumen before the operation, but that which was in the bladder at the time the autopsy was made contained both. He had therefore been led to believe that, in a large number of cases, what had been called septic symptoms had been due to renal changes. He regarded prolonged etherization as unsafe, and, if there was evidence of renal disease, as contraindicated.

Dr. Dudley also presented

A SLOUGHING FIBROID

removed from a patient, aged forty-three, who had borne ten children. She had suffered from pain and hemorrhage for nearly a year before he saw her. There was double laceration of the cervix. The fibroid was removed by means of the spoon-saw from the anterior wall of the uterus, close to the fundus.

The patient had intermittent heart-beat, and also an aortic murmur, besides about ten per cent. of albumen in the urine, which cleared up under the influence of citrate of potash and infusion of digitalis.

This patient took a small quantity of ether without unfavorable symptoms, and he intended to again administer it and subject her to an operation for repair of her perineum.

UTERINE POLYPUS, WITH ENLARGEMENT OF THE ORGAN, TWO YEARS AFTER THE MENOPAUSE.

Dr. Dudley also presented a small polypus removed from the anterior wall of the body of the uterus of a woman, aged fifty-four, who had been past the menopause two years. The cervix was really a senile one, and he divided it sufficiently to enable him to dilate and remove the polypus that he had previously recognized lying within the cavity of the cervix. The uterus measured four inches in depth.

Dr. Boldt referred to three cases in which acute renal changes were found, while the symptoms were supposed to be due to septicæmia. He also recalled two cases of polypus occurring after the menopause.

The Society then went into executive session.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 17, 1887.

A. Jacobi, M.D., President, in the Chair.

The President acknowledged the receipt of

A PORTRAIT OF THE LATE GUNNING S. BEDFORD, M.D.,

presented to the Academy by the family of the deceased, and read extracts from a printed memoir giving a brief biographical sketch of the distinguished Fellow.

On motion by Dr. J. A. Andrews, the thanks of the Academy were given to the family of the late Dr. Bedford for their beautiful and highly acceptable gift.

Dr. T. Mitchell Prudden then read a paper (see p. 341) on

BACTERIA IN ICE, AND THEIR RELATIONS TO DISEASE, WITH SPECIAL REFERENCE TO THE ICE-SUPPLY OF NEW YORK CITY—AN EXPERIMENTAL STUDY.

The President invited Dr. Francis Delafield to open the discussion, who said it seemed to him that the paper was one which called, not for discussion, but for commendation.

Its author had presented, not theories, but facts—facts so novel in their character, so carefully observed, and so clearly stated, and the deductions drawn from these facts had been made with so much conservatism and so little disposition to give more weight to them than they really deserved, that, while he found in the paper matter for the most earnest consideration, he could find concerning it nothing more to say.

Mr. Brennemann, on invitation, continued the discussion, and said that his investigations had been in the direction of chemical examinations of water. But it seemed to him that the author of the paper had thrown a flood of light upon the question of the contamination of ice. The possibility of the contamination of ice was a question that had often been discussed, yet in scarcely any of the annual health-reports had it been dwelt upon.

He had been specially interested in the determination which the author of the paper had made with reference to the resistance offered by specific bacteria to freezing; and he had been led to think of that peculiar instance, the epidemic at Plymouth, in which there had never been afforded a better demonstration of the resistance of the typhoid-fever bacillus to the influence of cold than was seen in the region ascribed to the origin of the disease.

It was certain that the points brought out in the paper were, many of them, the data for which investigators had been waiting in the discussion of the question of the production of disease by ice.

The question of the relation of biological tests to the purity of drinking-water was one that had been watched with interest by chemists; and as these had slowly come under their attention, there had been great hope that they would add the element of confirmation to chemical analysis of water. But he thought it must be concluded that, at the present time, it was impossible to fix the limit concerning the number of bacteria which would represent the limit of safety with regard to water—the absolute number of bacteria found by culture-experiments. There was no line of agreement, at present, between the chemical and the biological tests, concerning number, and he regarded it as impossible to say what interpretation should be given to this result.

But when it came to the question of quality by filtration, as compared with water, for example, furnished by artesian sources, then we have a valuable test in biology that has led to the filtration-process, upon which Frankland has placed great reliance. From daily examinations, there was reason to believe that, demonstrated by chemical and biological study, the *Croton water* should be regarded as a candidate for improvement.

The President congratulated the Academy and himself that they had been honored with the paper by Dr. Prudden. He then said that he had been looking up the literature of the subject, and had found it to be very limited, of which the following were extracts :

Dr. Miguel published researches on the vitality of bacteria in mountain-air and under the influence of cold temperature in the *Semaine Médicale*. He quoted the extract found in the *Centralblatt für Allg. Gesundheitspflege*, 1884, iii., 316 :

"Cold was not particularly a germicide. In a block of ice weighing fifty kilograms (one hundred pounds), taken from the Lake de Tour, Miguel found, after an interval of eleven months, seven hundred and fifty thousand living bacteria. Atmospheric microbes resisted the effect of a cold temperature of 100° C. (=148° F.), to which they were exposed through thirty-six hours. This intensely cold temperature was produced by the rapid evaporation of liquid sulphuric acid and liquid nitrous oxydol. But their resuscitation was slow, and took place on culture-fluids after three days only. In ten cubic metres of air he also found, at an altitude of four to seven thousand metres, no bacteria; on the Thun Lake, five hundred and sixty metres, 8 bacteria; near Hôtel Bellevue, five hundred metres, 21 bacteria; in a room of the hotel, 600 bacteria; in the Park of Montsouris, 7,600 bacteria; in Paris, Rue Rivoli, 55,000 bacteria."

From these researches he should conclude that if ice were to be free from bacteria it ought to be secured from altitudes of at least fifteen hundred feet.

Freudenreich has arrived at similar results, which he published in *Revue Scient.*, ii., 384, and which the President quoted from *d. Viertej. f. öff. Ges.*, xvii., supplement, 17.

Dr. J. A. Andrews said that while making some observations he found that pus, when frozen, was viable at the end of *three* weeks, as successful inoculations could be made with it in the cornea of rabbits, where it produced the characteristic bacteria of suppuration. Still later, that the staphylococcus was viable after the freezing had been maintained *seven* weeks.

The Academy then adjourned.

Emmenagogue Action of Oxalic Acid.—Dr. Poulet (*Gazette Hebdomadaire*, 1886, No. 20) extols oxalic acid as the best of all emmenagogues. It does not, however, he admits, abolish the pain experienced by many women in the discharge of the menstrual function, and it is, of course, inoperative in amenorrhœa consequent upon organic disease. The dose in which he prescribes it is one teaspoonful every hour of a mixture containing thirty grains of oxalic acid, about six ounces of water, and two ounces of syrup of orange-peel.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, March 4, 1887.

George F. Shrady, M.D., President, in the Chair.

Dr. George L. Peabody reported a case of

CYSTIC SARCOMA OF THE CEREBELLUM, WITH SECONDARY HYDROCEPHALUS, WITH THE SPECIMEN.

J. R——, fourteen years of age, a native of the United States, came under my care in the New York Hospital on June 7, 1886. There was no family history. He denies rheumatic, malarial, specific, nephritic, and alcoholic histories. He had measles at two years of age. He has always been a bright, healthy child. He was born with a rather large head. Two years ago he was laid up for two months with much headache and vomiting, and lost his appetite. He recovered from this, and was well until eight months ago, when he commenced to have much headache and vomiting. His eyes were very sensitive to light, and gradually he commenced to lose his eyesight, and at the end of two months, he had become totally blind. He has remained so ever since. In the last three weeks he has had several chills, but no fever, and no sweating. Two months ago he commenced to pass urine involuntarily, and has done this occasionally ever since. He has lost flesh and strength. His bowels have been constipated all the time. In the last few days, he has been quite stupid.

On admission, 8.30 P.M.—Temperature, 99.6° F.; respiration, 12; pulse, 96. He is poorly nourished; there is no œdema. Both pupils are dilated; neither reacts to light; he is totally blind. Patellar and plantar reflexes are slightly exaggerated. There is a little fluid in the right chest posteriorly. He is very stupid, has continually a listless expression. The head is large, measuring twenty-four inches in circumference; the lower part of face is heavy and dull. There is almost a total abolition of senses of smell and taste; pulse is of high tension, heart fairly forcible. His urine is high colored, neutral, 1.028, no albumen, no casts, phosphates in solution.

June 8th.—Temperature and pulse normal, respiration 13 and 14 to the minute. He passes urine and fæces involuntarily. Lies in a lethargic state all the time, is able to talk when aroused, but answers questions automatically he apparently has no reasoning power whatever; he sleeps a great part of the time.

June 9th.—His respirations vary from 12 to 14.

June 13th.—Ordered pot. iodide, gr. x. t. i. d.

June 17th.—Vomited twice to-day.

June 25th.—Condition much the same; perhaps a little brighter.

June 27th.—Patient vomited twice to-day, without apparent cause. His temperature this evening is 100.4°

June 29th.—Ordered iodide, gr. xxx. t.i.d. For last two days has been more stupid. From time to time convulsive twitchings of face and extremities are noticed. He vomited once to-day.

June 30th.—Vomited once. Evening temperature, 101.6°; respiration, 18; pulse, 110.

July 1st.—Ophthalmoscopic examination of eyes shows veins of retina enlarged and engorged with blood; the vessels of optic nerve almost obliterated. Temperature, 99.8°; respiration, 16; pulse, 105.

July 2d.—He has become very stupid. His gums are spongy. To-day he had a slight unilateral convulsion of right side; respiration was suspended during and after it for some moments. His face was much congested; the temperature of right side was higher than that of left. Temperature, 100.4 to 100.6°; respiration, 18 to 22; pulse, 116 to 94.

July 3d.—Temperature, 100 to 100.2°; respiration, 17 to 9; pulse, 112 to 106. Iodide decreased to gr. xv.

July 4th.—Temperature, 100.4°; pulse, 102 to 110.

His respiration varies from 6 to 12 per minute. It is somewhat peculiar; two deep inspirations are taken, then a period of rest varying from twenty to thirty seconds, then two inspirations again, quite rhythmically.

July 9th.—Pot. iodide discontinued. Urine reddish yellow, acid, 1.022, no albumen, few hyaline casts.

July 10th.—Ordered inunction of oleate of mercury daily.

July 18th.—Ordered gums painted with tr. benzoin daily, and inunctions of oleate of mercury discontinued. There is total abolition of senses of smell and taste.

August 6th.—Patient has become much brighter since last note. This morning he had a slight convulsion, with no after-effects.

August 16th.—Urine yellow, acid, 1.008, no albumen, negative microscopically.

September 12th.—His condition is about the same. He is very constipated urine and fæces are passed involuntarily. There is some slight rigidity of the arms; pupils are still widely dilated and do not react, his gums are very spongy, almost concealing the teeth. He takes only milk, but takes about sixty ounces of this every day. From time to time he has convulsions of both arms and legs, with no apparent after-effects. His respirations are still infrequent, varying from 6 to 12 per minute. He answers questions in the same slow methodical way. If asked whether it is night or day, he knows, but is unable to give any reason for his opinion.

September 22d.—Urine light yellow, neutral, 1.016, no albumen, negative microscopically.

October 10th.—Since last note he has become more stupid, does not now answer questions. His pupils are now both contracted and do not react. His convulsions are more frequent than formerly. He is hardly able to swallow milk. Pills when given to him dissolve in his mouth without any attempt on his part to swallow them. His face is slightly cyanotic, and there are numerous venous stigmata on it.

October 14th.—Urine amber, acid, 1.026, no albumen, many hyaline casts. He has failed very perceptibly since last note. Pupils still contracted. For the last two weeks he has been very hyperæsthetic, crying out whenever touched. His arms are flexed and rigid, and when an attempt is made to straighten them, he cries aloud. This morning his temperature is 104.4°.

October 15th.—Temperature, 106°; respiration, 16; pulse, 84. He continued to fail, and at 12.30 P.M., he died.

The *autopsy* was made one hour and a half after death.

Body is emaciated. Rigor mortis is absent. There is slight œdema of both lower extremities. There are two hemorrhagic areas in the skin just below the left inner condyle.

Head: The calvaria is very thin, its greatest circumference is twenty-two inches. There is a small normal clot in the longitudinal sinus. The convolutions over the vertex are everywhere distinctly flattened. The cavity of the left lateral ventricle is immensely increased in size. The right lateral ventricle in same condition. The third and fourth ventricles are also dilated. The right hemisphere of the cerebellum is greatly increased in size; its outer half seems on the surface to contain no cerebellar tissue at all, having the look and feeling of dense connective tissue; the inner half shows cerebellar convolutions on its surface. The entire right hemisphere is converted into a cyst which contains brownish serum. The wall of the cyst has an average thickness of about one centimetre. Its external measurements are 7 ctm. by 5 ctm. Its capacity is 33 c.c. The cyst is egg-shaped, its smaller end being directed toward the fourth ventricle. The left hemisphere of cerebellum is smaller than normal. Cyst presses upon roof of fourth ventricle, and upon its right lateral wall.

Peritoneum, diaphragm, and thorax normal.

Heart rather small, otherwise normal.

Lungs: Normal; bronchial glands are quite enlarged.

Kidneys: Capsules not adherent, surface smooth; organs apparently normal.

The mucous membrane of the stomach is distinctly thickened toward the pylorus.

Duodenum: The orifice of the common duct is pervious.

Intestines: The spleen, pancreas, liver, and gall-bladder normal. Pigmentation and depression at centres of acini of liver; anæmia and fat at their peripheries.

Urine found to contain no sugar.

By *microscopic examination* the fibrous-looking walls of cystic tumor is found to consist of small round- and spindle-cells in a rather abundant fibrous stroma which does not contain many blood-vessels, and in which are numerous aggregations of young inflammatory corpuscles and of pigment granules.

Dr. Peabody exhibited sections of the cyst-wall under the microscope, which showed the structure to be as he had described it.

He asked the impression of the members as to whether the tumor of the cerebellum by its pressure upon the roof and right wall of the fourth ventricle could have caused the dilatation of the general ventricular cavity of the brain. He believed that it was admitted by pathologists that anything which interferes with the return of venous blood from the choroid plexuses, or prevents the escape of serum from the ventricles, can cause secondary hydrocephalus. But the subject of the communication between the ventricular cavity and the outer surface of the brain was one upon which anatomists had not yet entirely agreed, and he therefore felt that he was not warranted in drawing positive conclusions as to the sequence of the lesions in the present case.

He regretted that the boy had come under observation so late that no study of his case could aid in settling this point with certainty.

Dr. A. H. Smith asked if there was not room for the supposition that the hydrocephalus was in existence when the sarcoma developed as a secondary disease.

Dr. Peabody said that such a possibility could not be denied.

Dr. W. H. Draper remarked that internal hydrocephalus might exist for many years without giving rise to symptoms.

Dr. Robinson asked how it was to be explained that in such cases, those of pressure on the fourth ventricle, sugar was sometimes present in the urine and sometimes absent; but, generally, albumen is not found, although, physiologically, its presence might be expected.

Dr. E. G. Loring was inclined to think that the shape of the head existed prior to the growth of the tumor in the cerebellum; for the child should have been blind almost from birth if the shape of the head was due to the tumor. Choked disk seldom is present in ordinary hydrocephalus where the sutures yield, no matter how great the accumulation of the fluid is. He thought that the child was hydrocephalic from birth, and that the sarcoma was a secondary occurrence.

Dr. Peabody also reported a case of

DOUBLE OVARIAN CARCINOMA IN A PREGNANT WOMAN, WITH SPECIMEN.

F. B——, thirty-four years of age, a native of Russia, married, and of no occupation, was admitted into the New York Hospital on June 27, 1884. She speaks a very imperfect German, and the only facts that could be learned from her were: That she had had a severe cough for more than three months; had spat up blood; had severe pain in the heart for two months, with great shortness of breath of late. She says she has been pregnant for at least six months.

On admission.—Patient is very poorly nourished. She is cachectic and sallow. She has the appearance of a woman of fifty years of age. There is marked œdema of the feet. Patient suffers greatly from dyspnœa, and cries out loudly with pain, which she refers to her chest.

The veins of the face and neck are turgid. At every inspiration there is retraction of the second and third intercostal spaces of the left side. Her pulse is of fair quality, but rapid.

Physical examination. — Anteriorly there is unequal expansion of the two chests; the right being more limited in its action.

On the right side there were roughened breathing, with dulness on percussion, and moist râles and ronchi.

On the left side respiration is exaggerated.

Posteriorly, on the right side, there is dulness, with tubular respiration.

On both sides there are numerous fine râles. The abdomen is protuberant and tense, and occupied by an ovoid tumor extending from the symphysis pubis to halfway between the umbilicus and ensiform cartilage. No uterine souffle nor fœtal heart-beat can be distinguished.

Ordered: Tr. digitalis, ℥. xv.; and whiskey, ℥ ss. q. three hours.

June 28th.—Temperature, 100.6° F.; respiration, 48; pulse, 148. Patient remained in same condition as on admission. She complained loudly at times of pain in the chest, and at several times suffered from cardiac syncope. Opium and stimulants relieved both those symptoms; but she gradually became weaker, and at 2.10 P.M. she died, on the day after her admission to the hospital.

The *autopsy* was made fifty minutes after death.

Inspection: Body poorly nourished. Rigor mortis absent; marked œdema of both lower extremities, more especially the left. Breasts are large; veins are prominent. Abdomen protuberant. There is a papilloma attached to the left labium magus. The uterus extends about three inches above the umbilicus. Both ovaries are about equally enlarged, lobulated, apparently solid. Vessels on the surface are distended. Ovaries measure 16 × 13 × 8 ctm. Their surfaces are somewhat irregular, but not very rough or nodular. The right ovary lies in the true pelvis. The left ovary lies partly in the pelvis and partly in the iliac region.

Diaphragm: Right side, fifth rib; left side, fifth space.

Thorax: The right pleural cavity contains a litre of brownish serum. The right pleura is studded by firm, white masses, cartilaginous in feel, some of them with caseous centres, varying in size from a millet-seed to a green pea. On the left side are old adhesions below the apex. The pleura contains very few such nodules as described on the right side. There is no fluid on the left side.

Heart: The heart is rather small, the valves are competent, the muscular tissue is flabby.

Lungs: The bronchial glands of both lungs are enlarged, and contain numerous grayish masses. The mucous membrane of the bronchi throughout is thickened. Both organs are alike.

Spleen: The spleen is large and tough, measuring 17 × 9 × 4¼ ctm.

Stomach: The stomach is normal.

Bile-duct: The common bile-duct is pervious.

Intestines: The intestines are normal.

Kidneys: The left kidney-capsule not adherent; surface is smooth. There are numerous whitish masses, from the size of a pin's head to that of a green pea, surrounded by a zone of congestion, in the cortex of the organ. Markings are distinct. The right kidney in the same condition, but it contains fewer of the whitish masses found in the left kidney. There are several of these masses on the surface of the organ.

Liver: Centres of acini are pigmented; the peripheries are anæmic.

Uterus: The uterus is occupied by a fœtus four pounds and eleven ounces in weight, well developed, and partially macerated. The nails of fingers and toes are well formed. The amniotic fluid is brownish in color. The os is patulous and admits three fingers; the head of the child is presenting. On section, the large tumors occupying the site of the ovaries present areas of cheesy degeneration, surrounded by pinkish, fleshy tissue of firm consistency, and bountifully supplied with blood.

Microscopic examination.—Kidneys: Examined fresh on section, are seen to contain a great deal of fat in the convoluted tubes. After hardening pieces in alcohol, sections through the whitish nodules are found to reveal ordinary encephaloid cancer.

Ovaries: Numerous sections from various places in both ovaries reveal the ordinary tissue of encephaloid carcinoma.

Liver: One similar nodule is found.

Lungs: Both lungs and bronchial glands show extensive invasion by similar growth.

Dr. Peabody further said that primary cancer of the ovary was well recognized, though infrequent; and that cancer was present in *both* ovaries in a considerable proportion of the recorded cases; but that, so far as he was aware, this case was unique, in that it showed the coincidence of pregnancy with cancer of both ovaries.

Ovarian cancer was usually, as in this case, of the encephaloid variety, and generally of rapid growth.

Dr. Peabody showed sections under the microscope from both ovaries, lungs, bronchial glands, liver, and kidneys, in all of which the carcinoma tissue was very well marked.

Dr. J. B. Hunter remarked that the specimen and case were especially interesting, because it was evident that some portion of ovarian tissue was competent to reproduce as late as nine months before death, while microscopical examination, as far as it had been carried, had failed to detect any ovarian tissue remaining. He had never met with a case of ovarian carcinoma in connection with pregnancy.

FACIAL ERYSIPELAS; IS IT CONTAGIOUS?

Dr. W. H. Draper mentioned a case of death from erysipelas of the head and face, which ran a more rapid course than any he had ever seen.

A man was admitted to the New York Hospital, a week ago, who was found to have chronic diffuse nephritis, and who suffered chiefly from the characteristic uræmic dyspnœa. He was relieved of his urgent symptoms, and was apparently doing very well, when he became very restless during the night, and was found, several times, to have thrown his head through between the bars at the head of the iron bedstead, from which position he had to be released. Night before last he was found with his head in that position, and when released it was discovered that he had bruised his left eye rather severely, and that there was an abrasion of the skin. When the house-physician saw him, in the morning, there was an erysipelatous blush about the wound, and this spread with such rapidity that when Dr. Draper saw the patient, in the afternoon, the entire left side of the face presented the characteristic appearance of acute erysipelatous inflammation, and it had also extended upon the scalp, over the left ear, and had invaded slightly the right side of the face. His breathing was comatose, pulse rapid, and temperature high. By midnight the entire face was involved, and also the scalp, and he died at two o'clock in the morning, the entire course of the disease continuing scarcely more than twenty-four hours.

There had been *seven* cases of erysipelas in this ward since January 1st, having been introduced by a case sent over from the surgical to the medical side.

A man died suddenly last week with heart disease, who had severe erysipelas from which he was convalescent. The ward had been closed and was being disinfected.

Dr. Draper mentioned these cases because he thought that medical cases of erysipelatous inflammation of the face—idiopathic erysipelas—were, by some, regarded as non-contagious. Of course, the case first mentioned was one of traumatic erysipelas.

Dr. George L. Peabody remarked that there had been nine cases of erysipelas following lobar pneumonia

in the hospital since last January. In one case there was secondary meningitis and death.

Dr. Draper said that he had a case in the female ward where the facial erysipelas followed pneumonia, occurring first on one side and then upon the other. Now she has purpura, and his suspicion was that she might have ulcerative endocarditis.

Dr. Beverley Robinson said that several cases of erysipelas had recently occurred in the medical wards of St. Luke's Hospital. He would mention one case that had special features of interest. A man, fifty-five years of age, who had been in the New York Hospital previously, gave the history of a small cerebral hemorrhage on the right side. His general condition was such that he did not require special attention, when he developed glandular swelling of the neck under the jaw on either side, without reddening of the skin. There had been in the ward a case of erysipelas, but, as there was no redness of the skin, Dr. Robinson did not regard this as a case of erysipelas at that time, nor did he regard it as a case of mumps. The swelling increased somewhat, was considerably painful, and at the end of twenty-four or forty-eight hours the patient died suddenly.

The autopsy showed that the glands underneath the jaw on either side, and about the larynx and trachea, were infiltrated with pus inspissated in character. In the larynx there was a certain amount of œdema, and there was a ragged ulcer that presented none of the appearances of tubercle or syphilis, and there was no evidence of constitutional syphilis. From the suddenness of the death, and the peculiar infiltration of the glands, without redness of the skin, he regarded it as a case of Ludwig's angina. Dr. Ferguson, who made the post-mortem examination, was inclined to regard it as a case of erysipelatous inflammation, and thought that the ulcer was the door of its entrance. He would ask whether or not the idea of erysipelas should be eliminated from the case, and whether Ludwig's disease was anything more than an erysipelatous inflammation of the subcutaneous cellular tissue in that locality.

Dr. Kinnicutt said that Dr. Robinson's case accorded very well with Ludwig's angina, which was believed to be an idiopathic infectious cellulitis.

Dr. A. H. Smith asked Dr. Draper if there was any connection between the kidney disease in his case and the erysipelas. He had seen very severe erysipelas in diabetics.

Dr. Draper thought that the occurrence of erysipelas in the course of chronic Bright's disease was common; and, until the disease was proved to be a germ disease, it was regarded as one of the secondary inflammations liable to occur with the chronic renal affection, the same as pericarditis, pleurisy, etc.

But of late he had been disposed to regard the occurrence of erysipelas in these cases as due rather to the fact that persons having chronic Bright's disease also had an exaggerated susceptibility for the reception of the erysipelatous germ; and so he thought the occurrence of severe forms of erysipelas in the course of diabetes could be explained; the tissues are in the condition which renders them an easy prey to the ravages of the germ.

Dr. R. F. Weir, in connection with the remarks made by Dr. Peabody and Dr. Draper, asked whether it was not proper to put on record

A PROTEST AGAINST THE RETENTION OF ERYSIPELATOUS PATIENTS IN THE WARDS

of hospitals for treatment. He thought that in their own institution it was a decided fault; that it was wrong that such patients should be treated in either a medical or surgical ward.

Dr. Draper agreed with Dr. Weir, and believed that erysipelas is always a germ disease, whether it comes into the hospital or is developed in the wards within the hospital, and that it should be treated the same as when it occurs with the distinct history of traumatism.

Dr. E. G. Loring asked if the germs were not in the hospitals when the patients were carried in.

Dr. Draper said that a great many cases of erysipelas were brought in.

Dr. Loring: But does the development of the disease depend upon the presence of germs within the hospital or upon the presence of conditions in the patient which will allow them to grow upon him?

Dr. Draper thought that the latter was probably true.

Dr. Loring said that he should therefore think that all the patients in the wards were just as much exposed while in the hospital as after the occurrence of a case of erysipelas.

Dr. Weir believed that facial erysipelas could be considered as a contagious disease, whether it occurred idiopathically or otherwise; but he also thought that very nearly all these cases were traumatic, starting from only very slight abrasions perhaps.

Dr. Peabody asked if anyone had seen erysipelas develop in a surgical case from a so-called idiopathic case; in other words, has phlegmonous erysipelas been distinctly known to follow infection by facial erysipelas?

Dr. Weir had seen such transmission in the old New York Hospital, and yet the evidence was deficient from the fact that it could not be said positively whether or not a different germ acted on the second case. Still, he would feel that his patients with open wounds were in an unsafe position with a case of facial erysipelas in the same ward.

Dr. Robinson said that in his ward there were two or three cases of facial erysipelas, and the man had the pathological conditions that were declared to be erysipelatous in character. The query then arises, Can we have erysipelatous inflammation of the cellular tissue and involvement of glands and formation of pus without reddening of the skin, or is Ludwig's disease anything more than erysipelas affecting the tissues beneath the skin?

Dr. E. D. Hudson asked, How does facial erysipelas infect a ward? Such cases would seem to indicate that the disease can be prevented from producing infection; and some do say so, and claim that it is a localized inflamed area of the skin at first, from which it extends through the medium of the lymphatics. So if the skin is washed with germ-destroying solutions, the disease will be arrested and the power of infection removed.

Dr. Peabody said that there seemed to be in erysipelas a disease which affected the whole system, but at the same time he must say that, practically, he had seen quite a large number of cases in wards in hospitals without the disease spreading to anyone or becoming infectious in any way. He did not think, however, that this could be used as an argument for non-contagiousness.

Dr. Weir mentioned a case that might shed a little light on the subject. He removed glands from the neck and from the axilla of a patient, and erysipelas appeared in the lower wound, the upper wound remaining entirely uninfected. That would show that the disease is a rather local affection.

Dr. Draper's experience accorded with Dr. Peabody's with regard to the spread of erysipelas in medical wards. He could not recall an instance in which it had spread either to nurse or to other patients. But he knew that there were well-authenticated cases in which patients sick with erysipelas had communicated erysipelas to their attendants.

The remark of Dr. Peabody, concerning the occurrence of erysipelas in patients who had had pneumonia, was very interesting in view of the fact that the clinical history of facial erysipelas is strikingly like that of pneumonia, as regards the febrile portion. It lasts about the same length of time and defervescence takes place suddenly, as in pneumonia.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 13 to March 19, 1887.

GRAY, WILLIAM W., Captain and Assistant Surgeon. Leave of absence further extended two months. S. O. 62, A. G. O., March 17, 1887.

CARTER, WILLIAM F., Captain and Assistant Surgeon. Leave of absence extended four months, on Surgeon's certificate of disability. S. O. 57, A. G. O., March 11, 1887.

POINDEXTER, JEFFERSON D., First Lieutenant and Assistant Surgeon (recently appointed). Ordered for temporary duty at United States Military Academy, West Point, N. Y., relieving Captain Richard W. Johnson, Assistant Surgeon, who will return to his proper station (Fort Adams, Rhode Island). S. O. 62, A. G. O., March 17, 1887.

Official List of Changes in the Medical Corps of the United States Navy for the week ending March 19, 1887.

PARKER, J. B, First Surgeon. Ordered to the United States Steamship Ossipee.

SIEGFRIED, C. A., Second Surgeon. Ordered to Baltimore, Md., on special duty.

HUGG, JOSEPH, Third Surgeon. Placed on Retired List, March 17, 1887.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 19, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	5	4
Scarlet fever	44	11
Cerebro-spinal meningitis	4	4
Measles	177	29
Diphtheria	108	57
Small-pox	14	1
Yellow fever	0	0

QUACKING SOUNDS IN THE EAR.—Dr. W. S. Parker, of Piqua, O., writes: "In THE MEDICAL RECORD of August 2, 1884, I reported a case of 'quacking sounds in the ear.' To-day, at noon, the subject of the report was taken suddenly with a violent pain in the right side of the head, within three minutes she was unconscious, and in twenty minutes was dead. Being in the immediate neighborhood I saw her at once, and found the following conditions: Stertorous breathing, feeble pulse, protruded tongue, and cold and blue extremities. The right pupil was dilated, while the left was contracted and did not respond to light. The patient had been in her usual excellent health. In the light of results, I am of the opinion that it was a case of ruptured aneurism, and that the sounds were due to the presence of the aneurism."

THE PROPER WEIGHT OF MAN.—Professor Huxley asserts that the proper weight of man is 154 pounds, made up as follows: Muscles and their appurtenances, 68 pounds; skeleton, 24; skin, 10½; fat, 28; hair, 3; thoracic viscera, 3½; abdominal viscera, 11; blood which would drain from the body, 7. The heart of such a man should beat 75 times a minute, and he should breathe 15 times a minute. In 24 hours he should vitiate 1,750 cubic feet of pure air to the extent of one per cent. A man, therefore, of the weight mentioned, should have 800 cubic feet of well-ventilated space. He should throw off by the skin 18 ounces of water, 300 grains of solid matter, and 400 grains of carbonic acid, every 24 hours; and his total loss during that period would be 6 pounds of water, and a little more than 2 pounds of other matter.—*The Hospital.*

THE EAST INDIA CONSUMPTION CURE.—Dr. James S. Cooley writes that the following is the recipe for a "consumption cure" which has enjoyed some popular reputation: Ext. Asiatic cannabis sativa, 2 oz.; ext. Asiatic hashish, 3 oz.; verbena hastata, 2 dr.; ext. diosma, 3 dr.; powdered cinchona bark, 2 oz.; ext. blood-root, 3 oz.; mullen, 1 dr.; loaf sugar, 1 lb.; rum or gin, 8 oz.; water, 24 oz. The writer sent the formula to Dr. Squibb, who replied that there were three of the ingredients with which he was not acquainted, but that it would be impossible to make a fine powder of the others, as the formula directed. The proprietor, who advertised his remedy—in a religious journal, of course—promised to send the ingredients in proper form for $3.

A NEW COLLODION.—The *Journal de Médecine* publishes a notice on a new collodion which is antiseptic and facilitates cicatrization. This collodion does not cause inflammation, and may be substituted for collodion containing gun-cotton in treating wounds and bruises. Like traumatacene, it is efficacious in relieving neuralgic pains, acute or chronic rheumatism. The affected parts should be sponged with it every twenty-four hours, and in serious cases every six hours. If strips of linen or silk be soaked with this collodion an excellent plaster is obtained, which equals that prepared with ichthyocolla, commonly called English court-plaster. It is prepared according to the following formula: Mastic in globules, 3 grammes; balsam of Peru, 1 gramme; narcotin, 1 gramme. Each substance is separately ground; 5 grammes of chloroform are added. The mixture is shaken from time to time, and allowed to rest after solution.

MICRO-ORGANISMS IN THE BLOOD, IN CLOSED CAVITIES, AND IN VARIOUS SECRETIONS.—Recent researches have led Eiselsberg to the following conclusions, which agree with those of Ogston, Rosenbach, and Passet: 1. In the blood of healthy persons there are no micro-organisms, those forms described by Hoffman as micro-organisms being products of the destruction of blood-corpuscles. 2. In the blood of those suffering from septicæmia or pyæmia are found mostly pus-cocci, chiefly the Staphylococcus pyogenes albus, sometimes the Staphylococcus pyogenes aureus and streptococcus, or the three kinds mingled. 3. In the blood of erysipelas patients the specific pus-coccus does not appear. This agrees with the experience of Fehleisen. 4. In the blood of patients with fever, who are suffering from wounds, but with no connection between the two, there are found no pus-cocci. 5. In closed pus-cavities (phlegmons, carbuncles, osteo-myelitic and myelitic abscesses, empyema, tonsillar abscesses, etc.) there always appear the various kinds of pus-cocci, singly or mixed. 6. In blisters he found no cocci, nor in ovarian cysts, nor echinococcus cysts, nor cysto-fibroma. When Eiselsberg failed to find cocci in the blood of septicæmia or pyæmia, he ascribed it to the circumstance that not every drop of the blood contained them.—*Centralblatt für Chirurgie.*

THE TREATMENT OF WHOOPING COUGH.—Dr. P. Suerder has treated thirty children suffering from whooping-cough with nasal insufflations of finely powdered boric acid and roasted coffee. Dr. Arntzenius, of Amsterdam, says that in that city whooping-cough is endemic, there having been about twenty-five hundred cases in 1885, with a mortality of 7.6 per cent. He claims that the treatment of these cases with rarefied air has been attended with much success.

ON BACTERIA IN ICE, AND THEIR RELATIONS TO DISEASE, WITH SPECIAL REFERENCE TO THE ICE-SUPPLY OF NEW YORK CITY.

AN EXPERIMENTAL STUDY FROM THE LABORATORY OF THE ALUMNI ASSOCIATION OF THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

BY T. MITCHELL PRUDDEN, M.D.,

DIRECTOR OF THE LABORATORY.

(Concluded from page 350.)

Snow-ice and transparent ice.—If we look at the blocks of ice as it is being distributed from the wagons, we find a considerable variety in their appearance. In some cases the blocks will be clear and transparent throughout. This is most apt to be the case with river ice, while lake and pond ice is more apt to be somewhat whitish in appearance from the distribution through it of larger and smaller air-bubbles. This is, however, by no means always the case.

Again, the ice-blocks may be, for the most part, either transparent or slightly bubbly, while on one side—that side which was uppermost as the ice was forming—there will be a layer, of from one-half to three inches thick, which is white and opaque and more or less friable. Its opacity is not at all due to any impurities which it contains, but to the fact that it is thickly crowded with air-bubbles, around which the ice is irregularly crystallized. This is called "snow-ice," partly, doubtless, on account of its appearance, and partly because of its mode of origin.

Mode of formation of snow-ice.—After the first film of ice is formed at the surface of the water, the process of freezing goes on downward, as the heat from the water below radiates off into the colder air above. If anything occurs to prevent this radiation of heat upward, the formation of ice ceases. This happens, of course, if the temperature of the air rises above the freezing-point, but it also occurs if any considerable amount of snow collects upon the surface of the ice already formed. The air, which is caught in innumerable tiny cavities between the snowflakes as they settle upon the ice, acts as a blanket to prevent radiation, and thus the formation of fresh ice below comes to a stand-still, even though the weather be quite cold. Snow is for this reason a great bugbear to the ice-harvesters. It must be gotten rid of at any cost, for, if not, the crop stops growing. Now two courses are open to the ice-farmer: If the already formed ice is thick enough to bear he can go on with his horses and scrape the snow off from his ice-field, and this, as the writer is informed, is usually the preferable course when it is practicable and there is promise of plenty of cold weather, because if he gets rid of the snow he may get ice which is clear and transparent throughout, and which, at least for household and drinking purposes, is most popular and valuable.

But if, when the snow comes, the already formed ice is not thick enough to bear, or if the weather prospects indicate a lack of cold, so that he fears lest the ice may not be thick enough for profitable handling, he cuts a series of small holes in various places over his ice-field, the water from below pours up over the surface, merges with the snow and freezes. In this way, while the non-conductibility of the snow-blanket is largely reduced, he gets an additional layer of ice on top. This operation is called "flooding" or "bleeding" the ice. But this partially melted snow-layer is never transparent, because a large number of air-bubbles will still remain entangled in it. This is one way in which snow-ice is formed, on the top of the blocks as we see them in the market, and it is white on account of the large number of entangled air-bubbles.

Very frequently the snow is followed by rain, and then a snow-ice layer may form on top by natural means, from the water which falls directly upon the ice or runs onto it from the banks.

If the ice is thick enough, so that the harvester can afford to do it, this top snow-layer may be planed off, though at considerable expense, leaving transparent ice. But it is the practice of most harvesters to leave a layer of from one to three inches in thickness of the snow-ice on the top of the block, because it forms, on account of its enclosed air-bubbles, a protective layer on one side which retards melting and waste of the clear ice both in the storage houses and in transportation.

It is a frequent practice of some of the more responsible dealers to chip off most of this snow-ice layer before it is weighed out to customers. The temptation to not remove this snow-layer, but to weigh and deliver it with the rest is, however, so great, particularly in years when the supply is short, that it is very often not successfully resisted, as anyone may convince himself who will take the trouble to notice the blocks of ice which are left at houses through the city. Ice having a large amount of snow-ice in the block is known in the slang of the handlers as "fat" ice.

Sometimes when forming both the ice and snow sink a little, and a considerable depth of water covers both and freezes; then the snow-ice will be embedded in the block in the form of a dense, bubbly streak between layers of transparent ice.

Bubbly streaks in ice.—Still again, one frequently sees strata of air-bubbles enclosed in the block of ice, which lie parallel to the surface but below the snow-layer in the transparent ice which was formed downward. These are apparently due to the accumulations beneath the ice of air-bubbles which have freed themselves from the water as it freezes, or, in ponds, in part at least, from decomposing matter at the bottom, and finally became enclosed as congelation proceeded downward. These streaks or bands of enclosed bubbles which lie between bands of clear ice may be narrow or broad, and a series of them may often be seen lying close together with clear ice-bands between them, like the strata of sedimentary rock.

These alternating bands of bubbly and transparent ice give us a very interesting record of the varying temperature during the time in which the ice was forming. For it appears that if the temperature is low for a considerable period, so that the formation of ice downward in the water steadily proceeds, this ice, particularly in rivers or where the water is in motion, will be apt to be quite transparent, containing but a few scattered bubbles. If, however, the temperature rises, so that the ice does not form at all or makes but slowly, bubbles are apt to collect on the under surface and become enclosed in streaks when ice begins again to form. Thus we may have a series of narrow, closely packed, alternating, transparent, and bubbly layers, as a record of the nightly freezing and

the daily thaw, or a series of broader bands when the changes of temperature follow one another less closely.

Disintegration of ice.—Finally, ice which has been exposed to a moderately warm temperature out of doors is apt to undergo a gradual molecular disintegration, and long air-bubbles may appear in it along the sides of the ice-crystals of which, though invisible, the solid ice is composed. As these ice-crystals, after the first surface film is formed at the commencement of the freezing, lie with their long axes perpendicular to the free surfaces of the ice, the long bubbles caused by disintegration lie in the same direction.

This process of disintegration is called "combing," and large masses of ice may in this way become very rotten and friable, while retaining their external form, either with or without the collection of long air-bubbles between the partially melted ice-crystals. With air which enters the ice in this way by its disintegration, and with vacuoles which look like air-bubbles, but are caused by the localized melting of small portions of ice within the solid block, the present study has nothing to do. For a long series of analyses of ice in this condition, made by the writer, shows, as was to be expected, that the presence of these disintegration air-bubbles and of vacuoles has no relation whatsoever to the number of bacteria present in the ice.

Lake and river ice.—Exactly why pond and lake ice should be apt to contain more scattered air-bubbles than river ice, and hence to appear more or less whitish, is not altogether clear, nor is it by any means always the case. But the tendency seems in a measure due to the absence of running currents of water, which in rivers would tend to carry off the air-bubbles, while in still ponds and lakes these would be more apt to be caught and frozen where they lodged beneath the ice.*

Sometimes large volumes or "blebs" of air or gas are seen beneath the ice of ponds. The contents of these blebs are, in some cases at least, inflammable, as has been seen by making a small hole in the ice above them and applying a match as the gas is forced up. This gas, of course, and doubtless a considerable proportion of the smaller bubbles, in some cases, is the result of vegetable decomposition at the bottom of the water, a process which, as is well known, is sometimes in summer very active.

Popular prejudice against bubbly ice.—The popular prejudice against white—that is, bubbly—ice, which is very strong and, so far as we have hitherto known, as unreasonable as it is potent, is apt to work against some of the very best sources of ice-supply, namely, ponds and small lakes. "Clear ice," say the observant consumers, "we can look right through and see for ourselves that there is nothing bad in it. We can't see through white ice, and there must, therefore, be something in it, and we don't want ice which is so full of something or other that we can't see through it." It is in vain that the laws of optics are called to the help of the ice-dealer; in vain that the "something" is again and again demonstrated to be nothing more harmful than air; in vain that purity and whiteness in snow are shown to be compatible qualities. One consumer trusts his own senses rather than the refinements of science; another, perhaps at last convinced, still urges that the market value of winter wind or decomposition-gas is not rated at ten dollars per ton.

It was primarily in view of this condition of affairs that throughout the following series of ice-analyses the writer carefully separated the samples of ice subjected to examination into two classes: First, clear ice, or ice which contained but a few scattered bubbles; and, second, snow-ice and very bubbly streaks formed beneath the surface.

This distinction between the snow and bubbly and the transparent ice, which was made by the writer at first with a view of combating the popular prejudice against white ice, proves, after all, to be an exceedingly important factor in forming our opinion of the quality of a given ice-sample.

The first thing which strikes the observer, as he examines in detail the results of the analyses of the ice of both these classes, is the great variability in the number of living bacteria which ice, even from different parts of the same block, contains. This it is which makes a large number of analyses imperative, if we would arrive at general conclusions regarding the number of bacteria which ice from any given source contains. This unequal distribution of the bacteria in ice is not surprising, since the same inequality has been repeatedly shown to exist in water, owing doubtless to minute currents and eddies and incomplete mixing or distribution of the contaminating material.

Results of Analyses of Hudson River Ice.—Let us look first at the Hudson River ice, and for convenience we will make separate tables for the ice which is harvested immediately below Albany and that which is gathered in the region from six to fifty miles below.

Table XIII.—*Number of Living Bacteria in One Cubic Centimetre of Melted Ice from Various Points on the Hudson River, from Castleton, about Six Miles below Albany, to Rhinebeck, about Fifty Miles below.*

Transparent ice, 83 samples.		Snow-ice and very bubbly streaks, 34 samples.	
Number of living bacteria in 1 c.c. of the melted ice.	Number of samples.	Number of living bacteria in 1 c.c. of the melted ice.	Number of samples.
Less than 10	In 23 samples.	Less than 100	In 0 sample.
Bet. 10 and 50	" 22 "	Bet. 100 and 200	" 1 sample.
" 50 " 100	" 12 "	" 200 " 300	" 2 samples.
" 100 " 200	" 16 "	" 300 " 500	" 1 sample.
" 200 " 500	" 4 "	" 500 " 1,000	" 5 samples.
" 500 " 1,000	" 3 "	" 1,000 " 2,000	" 4 "
" 1,000 " 5,000	" 2 "	" 2,000 " 5,000	" 12 "
" 5,000 " 6,000	" 1 sample.	" 5,000 " 10,000	" 7 "
		" 11,000 " 12,000	" 2 "

In two cases only were samples found which contained in one cubic centimetre no bacteria at all.

Table XIV.—*Number of Living Bacteria in One Cubic Centimetre of Melted Ice from the Hudson River just below Albany.*

Transparent ice, 24 samples.		Snow-ice and very bubbly streaks, 12 samples.	
Number of living bacteria in 1 c.c. of the melted ice.	Number of samples.	Number of living bacteria in 1 c.c. of the melted ice.	Number of samples.
Less than 50	In 3 samples.	Less than 100	In 0 sample.
Bet. 50 and 100	" 3 "	Bet. 100 and 200	" 0 "
" 100 " 200	" 5 "	" 200 " 300	" 0 "
" 200 " 500	" 3 "	" 300 " 500	" 0 "
" 500 " 1,000	" 3 "	" 500 " 1,000	" 0 "
" 1,000 " 5,000	" 6 "	" 1,000 " 5,000	" 0 "
" 5,000 " 6,000	" 1 sample.	" 5,000 " 10,000	" 1 sample.
		" 10,000 " 20,000	" 4 samples.
		" 20,000 " 30,000	" 4 "
		" 30,000 " 40,000	" 1 sample.
		" 40,000 " 50,000	" 1 "
		55,000	" 1 "

It should be remembered that all of the analyses recorded here were made from specimens taken from different cakes of ice, and so far as possible from those cut in different places in the field. So that a fair sampling was insured.

The following table summarizes these results, giving the averages of the detailed analyses:

Table XV.—*Hudson River Ice.*

Source.	Number of samples.	Forms of ice.	Number of bacteria in 1 c.c.
All sources	153	Trans. & snow.	3,040
All sources	107	Transparent	398
	46	Snow	9,187
From 6 to 50 miles below Albany	83	Transparent	189
	34	Snow	3,693

* Many interesting facts about ice formation and characters may be found in the files of the very readable Ice Trade Journal, published in Philadelphia.

While the great difference in the bacterial content of ice taken from the region of Albany and that gathered farther down the stream is thus very evident, a still more graphic representation is afforded if we take the average numbers of living bacteria found in one cubic centimetre of both transparent and snow ice gathered at various points along the Hudson River and express them in a chart.

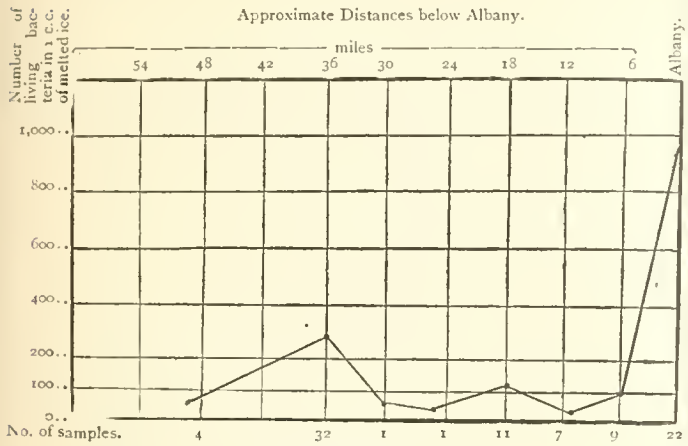

FIG. 1.—Transparent Ice.

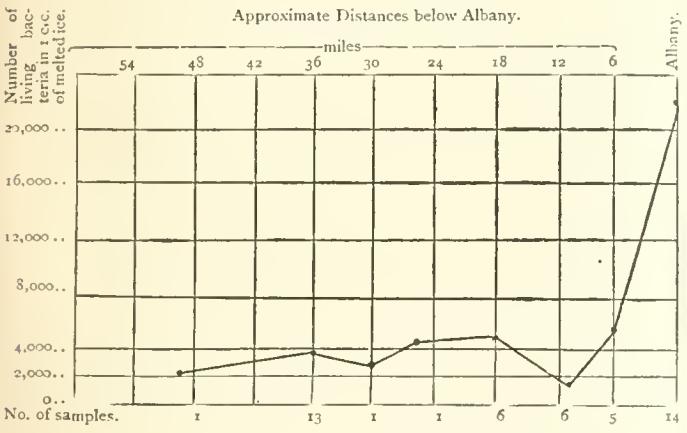

FIG. 2.—Snow Ice and very Bubbly Streaks.

These charts show with great distinctness that ice formed near Albany contains vastly greater numbers of bacteria than that formed at some distance below. It is evident, therefore, that by natural agencies the water of the river is freed to a certain degree from bacteria after running for some distance. Still, the average number of bacteria left in the ice is considerably above that which can be regarded as wholly safe.

It should be said, in justice to the Hudson River ice, that the crop of the winter 1885–86, from which most of the analyses above recorded were made, was of poorer quality than usual, because the season was an unfavorable one; but the careful selection by the writer of well-formed samples for analyses would partly, at least, offset the general unfavorable conditions.

So far as this series of analyses shows, the ice does not, as one might at first expect, get freer and freer from bacteria as the distance from Albany increases, but from six to fifty miles below Albany, with local fluctuations difficult to explain, remains very nearly the same. It, of course, presents some variation when cut below the smaller towns which drain into the river.

But a very much more extended series of examinations will be necessary before we can determine with any great degree of accuracy how far the river has to run below a source of sewage contamination in order that the water may, by freezing and other natural agencies, free itself to a proper degree from its bacterial contaminations, or if, indeed, it does so at all.

The remarkable difference in the bacterial contents of snow ice together with very bubbly streaks, and transparent ice, prevails in all parts of the river alike, and it is surprising, not only how constant the difference is, but also how abrupt the transition is in the ice-block between the few and the many bacteria, corresponding exactly to the line of demarcation of the clear and bubble ice. Thus in a series of examinations, made from snow ice or very bubbly streaks and very clear ice in the same ice-cake in various samples from the Hudson, we get results expressed in the following table:

TABLE XVI.—*Relative Number of Living Bacteria in 1 c.c. Transparent Ice and Snow Ice taken from the Hudson River, as shown by the Analysis of Adjacent Portions of the same Ice-blocks—Specimens from Various Parts of the River.*

	Source.	Greenbush, near Albany.	Castleton.	Barren Island.	Coxsackie.	German towo.
1	Transparent..	46	66	32	44	150
	Snow	10,020	5,184	520	12,642	9,234
2	Transparent..	3,192	92	122	92	919
	Snow	15,624	2,430	268	430	11,584
3	Transparent..	2,322	585	.....	676	9
	Snow	55,062	9,600	.....	4,294	114
4	Transparent..	218	.....	.....	.....	2
	Snow	9,690	.....	.....	.....	1,308
5	Transparent..	918	.....	.....	.....	.....
	Bubbly streak	26,049	.....	.....	.....	.....

These are only a part of the analyses made in this way, and are taken quite at random from the list. In no case was there an exception to the rule that snow and very bubbly ice contains a much greater number of bacteria than adjacent transparent ice from the same block.

The very bubbly streaks, although containing, as a rule, very many more bacteria than the transparent ice, still do not generally contain nearly as many as the top layers of snow ice.

RESULTS OF ANALYSES OF LAKE AND POND ICE.—Before attempting to explain this curious difference between snow ice and transparent ice, let us look at the results of the analyses of the lake and pond ice from the above-described sources.

TABLE XVII.—*The Number of Bacteria in Rockland Lake Ice.*

Transparent ice, 17 samples.		Snow ice, 5 samples.	
Number of living bacteria in 1 c.c. of the melted ice.	Number of samples.	Number of living bacteria in 1 c.c. of the melted ice.	Number of samples.

" 3,000 " 4,500.	" 3 "	" 5,000 " 6,300.	" 3 "

TABLE XIX.—*The Number of Bacteria in Swartout Pond Ice.*

Transparent ice, 16 samples.		Snow ice, 7 samples.	
Number of living bacteria in 1 c.c. of the melted ice.	Number of samples.	Number of living bacteria in 1 c.c. of the melted ice.	Number of samples.
Less than 10.....	In 13 samples.	Less than 100	In 2 samples.
Bet. 10 and 50...	" 1 sample.	Bet. 100 and 200.	" 0 "
" 50 " 100...	" 1 "	" 200 " 300.	" 1 "
" 100 " 200...	" 0 "	" 300 " 500.	" 2 "
" 200 " 300...	" 1 "	" 500 " 1,000.	" 1 "
		" 1,000 " 2,000.	" 1 "

A smaller number of analyses was made from Tuckahoe, Van Cortland, and Verplank's Point ice, but the tables are given for the sake of comparison.

TABLE XX.—*Number of Bacteria in Tuckahoe, Van Cortland, and Verplank's Point Ice.*

TUCKAHOE.

Transparent ice, 4 samples.		Snow ice, 4 samples.	
Number of living bacteria in 1 c.c. of the melted ice.	Number of samples.	Number of living bacteria in 1 c.c. of the melted ice.	Number of samples.
Less than 10.....	In 3 samples.	Less than 100.....	In 4 samples.
Bet. 10 and 50.....	" 1 sample.		

VAN CORTLAND.

Transparent ice, 5 samples.		Snow ice, 4 samples.	
Less than 10.....	In 3 samples.	Less than 100.....	In 3 samples.
Bet. 10 and 50.....	" 2 "	Bet. 100 and 200....	" 1 sample.

VERPLANK'S POINT.

Transparent ice, 3 samples.		Snow ice, 3 samples.	
Less than 10.....	In 3 samples.	Less than 10.....	In 3 samples.

It will be seen from the last table that while the specimens from Van Cortland and Tuckahoe were taken from different blocks and thus more fairly represent the ice, the samples in the case of Verplank's Point were all from a single block, taken from the pond as a sample before the ice-cutting season of 1886–87 began. But as it was only a single specimen, the value of the result is but moderate.

The same sharp contrast in the number of bacteria in transparent ice and snow ice, or very bubbly streaks, is found in lake and pond ice which we have seen in river ice, as may be seen by the following table :

TABLE XXI.—*Relative Number of Living Bacteria in 1 c.c. Transparent and Snow Ice from the Same Cakes —Specimens from Lakes and Ponds.*

Source.	Rockland Lake.	Swartout Pond.	Ice Pond.	Tuckahoe and Van Cortland.
Transparent	67	1	10	2
Snow	1,578	95	236	64
Transparent	190	214	1,512	24
Snow	1,260	367	5,520	54
Transparent	115	....	56	....
Bubbly streak.....	9,120	....	306	....
Transparent	14	....	....	....
Bubbly streak.....	1,368	....	....	....
Transparent	....	...	22	40
Snow	....	....	3,960	170

It will be seen from this table and the similar one constructed from analyses of the river ice, that the number of bacteria in the transparent ice affords no criterion of the number in the adjacent snow ice, and *vice versa*. So that in a cake of ice whose snow-layer contains an unusually small number of bacteria—as snow ice goes—the transparent ice may, on the other hand, contain an unusually large number ; and the converse is equally true. Taking all the analyses of the lake and pond ice together, there is a much larger number of samples containing no bacteria at all than in the Hudson River ice. This absolute freedom is in both cases always in transparent ice. Thus, in 16 specimens from Swartout Pond there were 4 in which one cubic centimetre of the ice was entirely free from bacteria. In 118 samples of lake and pond ice there were 8 containing no bacteria, while in 153 samples of Hudson River ice there were only 2 entirely free, and these were gathered from the lower part of the river.*

TABLE XXII.—*Lake and Pond Ice—Summary.*

Source.	Form of ice.	Number of samples.	Number of bacteria in 1 c.c.
Rockland Lake	Transparent....	17	181
	Snow	5	4,116
Swartout Pond	Transparent....	16	20
	Snow	7	565
Ice Pond	Transparent....	36	618
	Snow	15	2,469
Tuckahoe Pond.....	Transparent....	14	6
	Snow	4	63
Van Cortland Lake....	Transparent....	5	16
	Snow	4	81
Verplank's Point.....	Transparent....	3	5
	Snow	3	1

The exception to the rule that snow ice contains more bacteria than the adjacent transparent ice, which is seen in the result from a single cake from Verplank's Point, will be considered below.

If, for the sake of comparing the lake and pond with the Hudson River ice, we place the averages together, we have the following table :

TABLE XXIII.—*Relative Number of Bacteria in One Cubic Centimetre of Hudson River Ice and Lake and Pond Ice.*

Form of ice.	Hudson River, 153 samples.	Lakes and Ponds, 119 samples.
Transparent.....	389	318
Snow.....	9,187	1,636

If, however, in order to give the Hudson River ice its due credit we exclude the ice cut near Albany, we have the following table :

TABLE XXIV.—*Relative Number of Bacteria in One Cubic Centimetre of Hudson River Ice, from Six to Fifty Miles Below Albany, and Lake and Pond Ice.*

Form of ice.	Hudson River, 117 samples.	Lakes and Ponds, 119 samples.
Transparent.....	189	318
Snow.....	3,693	1,636

The summary of the last two tables is at first sight rather surprising, for we see that the average number of bacteria in a cubic centimetre of transparent ice from the lakes and ponds, free as they are from obvious sewage pollution, is still almost as great as the average in transparent ice from all parts of the river ; while if we exclude ice from Albany the average number in ice from the remainder of the river is even considerably less than that of the pond and lake ice.

If we look, however, at the transparent ice from the various lakes and ponds, we see that the general average is raised by the ice from Ice Pond, in which 618 represents the average, as against 78 which represents the average of all the other ponds and lakes taken together.

* *Maine Ice.*—A few samples of Maine ice from Gardner's Bay were examined. The average number (in one cubic centimetre) in transparent ice was 85 ; in snow ice, 250. One block showed in the top snow-layer in one cubic centimetre, 378 ; the middle of the thick transparent portion below gave 198 ; while the lower part of the transparent ice—*i.e.*, that which was formed last—contained only 37. The number of specimens examined was, however, so small—five—that inferences as to the bacterial qualities of the Maine ice should not be drawn from the results.

Now the Ice Pond ice, in the samples examined, was especially rich in the fluorescent bacillus, which, as experiments show, proliferates readily in water—even in boiled distilled water in the laboratory experiments. This fact, together with the partially stagnant character of the pond, with its large communicating swamp, would seem to fully explain the high average which is found here, especially when we remember how resistant is this species to the cold.

TABLE XXV.—*Showing Average Number of Bacteria in One Cubic Centimetre of Melted Ice from Various Sources as Compared with the Average Number in Croton Water during the Winter of* 1886–87, *when both were Examined.*

	Average number of bacteria in 1 c.c. of the melted ice.	Average number of bacteria in 1 c.c. of Croton water, winter 1886–87, 32 samples.
Transparent and snow ice and ice with very bubbly streaks, from all sources; 272 samples	2,033	243
Transparent and snow ice and ice with very bubbly streaks, from all sources except just below Albany; 236 samples	971	243
Transparent or slightly bubbly ice from all sources; 188 samples	363	243
Transparent or slightly bubbly ice from all sources except just below Albany; 164 samples	252	243

We see from this table, which summarizes the results of a large number of analyses from many sources, that if the bacteria in ice are of any significance at all, the snow-layer is to be avoided for drinking purposes, and also that the sewage of a large town makes a good deal of difference in the bacterial content of the ice gathered near it.

We are further led to the rather striking conclusion that if we use only transparent ice and avoid that which is harvested near Albany, sewage-polluted as the Hudson River is, we do not on the average get more bacteria than in our ordinary unfiltered winter Croton water. The significant difference in the *species* of bacteria in the two cases will be considered farther on.

Although the very bubbly streaks contain, as a rule, many more bacteria than the transparent ice adjacent to them, the proportion in real snow ice is almost always so much greater, that it alone appears to be of great importance in this respect. Indeed, the rule that very bubbly and snow ice contains more bacteria than transparent ice holds good only when the water from which the ice is formed contains a considerable number of bacteria. Thus, the only exception to the rule which has been encountered by the writer in this long series of examinations was in ice from Verplank's Point, in which, as will be seen from Table XX., the snow-layer contained a less average number of bacteria to one cubic centimetre than the transparent ice, and the number in both was very low. But the water from this pond, which was collected at the time the ice was secured, contained in an average of four analyses only 175 living bacteria.

BACTERIA IN SLIGHTLY BUBBLY ICE.—A long series of analyses made for this purpose have shown that this relationship between the number of air-bubbles and the bacteria in ice exists to an appreciable extent only when the air-bubbles are very numerous, as in real snow ice and in very bubbly streaks; while moderately bubbly lake ice, which has small bubbles scattered through it, so as to look whitish and opaque only in large blocks, does not show an appreciably larger number of bacteria than quite transparent ice from the same source. This will not seem strange if we examine carefully typical moderately bubbly lake ice, which looks quite opaque in large cakes; for we then find that in small pieces it is almost as transparent as the clearest ice, and that the number of scattered bubbles required to give a large block of ice an opaque whitish appearance is really very moderate indeed.

We thus see that the unreasonable popular prejudice against bubbly ice appears to have, after all, a real basis, so far as the snow-ice layers so frequent on the top of the ice-cakes are concerned; the ordinary opaque ice, however, with comparatively few bubbles, is apparently just as free from bacteria as the most transparent.

Such moderately bubbly lake ice, or ice from any source containing scattered bubbles, may on exposure become very much whiter; and very scantily bubbly streaks or bands in transparent ice may become, under the same conditions, so white and broad that, when viewed at a little distance in the block, they look like layers of sunken snow ice. But a close inspection in either case shows that this change is due to an internal disintegration of the ice around the air-bubbles by heat transmitted through the surrounding intact ice. In this way, as a little of the ice along the sides of the invisible crystals melts, and in so doing occupies less space than before, the air in the original bubbles expands to fill the vacuum, and the rarefied bubble becomes elongated to fill the long space between the crystals.

In this way a given plane of the ice-block, which formerly contained so few scattered rounded bubbles that they were almost invisible, or at least quite inconspicuous, may in a short time become the seat of a broad, palisade-like stripe. The insignificance of these long disintegration bubbles has been emphasized above. If a fragment of ice containing these rarefied bubbles, which are embedded in solid ice and not in communication with the external air, be put under water in a shallow glass dish and carefully watched as it melts, these disintegration bubbles may be seen to suddenly contract as they are freed by the melting of the ice around them and rise to the surface.

REASONS FOR EXCESS OF BACTERIA IN SNOW ICE AND IN VERY BUBBLY STREAKS.—Let us now see if this marked excess of living bacteria in snow ice and in very bubbly streaks over the solid transparent ice can be explained.

It was noticed by the writer, in the large number of analyses made of snow ice and also of the very bubbly streaks in clear ice, that two or three species of bacteria were almost always particularly abundant. The most common of these was the fluorescent bacillus above described. The other most common form is a short bacillus forming spreading iridescent colonies, not fluidifying.

Both of these bacilli are capable of performing vigorous movements in water, as may be readily seen under the microscope. Both of them grow much more abundantly on the surface of the gelatin where there is plenty of air, and if the air be cut off, as by laying a mica-plate on the surface of the gelatin where they are planted, their growth is very meagre. They are what are called aërobic forms of bacteria.

In view of this character, it seemed not improbable that these species, and perhaps others as well, would tend to make their way in the water toward the air-bubbles which might be collected at any point, and be caught here by the freezing of the water. If this were true, it would explain, in part at least, the curious fact of the excess of bacteria in bubbly layers of ice over the clear portions near by.

In order to test this hypothesis the following experiments were devised and executed. Three deep, flat dishes were carefully sterilized and filled about two-thirds full of sterilized water, in which had been thoroughly diffused some of the above-described fluorescent bacilli. It was found by an analysis of this mixture that one cubic centimetre of the water contained 21,384 living bacteria. Now I had gathered for this purpose, in a large clean flask on the morning on which these experiments were got under way, a quantity of clear, freshly fallen snow. This snow was obtained in the upper part of Central

Park, at a point as far away as possible from paths and roads, which were in a very clean condition, however, as they were just being cleared after the snow-fall. Analysis of the water obtained in melting this snow showed that it contained on the average only four bacteria to the cubic centimetre, a number so small as to be of no importance in this connection.

Now three small wads of this snow were made by tamping it firm with a clean knife-blade, and these were completely soaked with sterilized water. They were then dropped into the dishes containing the bacteria in the water, one wad into each. The dishes were then carefully covered, allowed to stand for about ten minutes in a cold place so that the snow would not melt completely in the water, and were then put into the refrigerator, where, within an hour, they were frozen solid.

It was found on examination of the dishes that in the centre of each lay the lump of snow, a little smaller, but otherwise not apparently changed, and enclosing many air-bubbles. From this snow-lump a large number of elongated air-bubbles radiated in all directions, while around the edges of the dishes was a zone of perfectly transparent ice. We thus have an almost exact experimental reproduction of the conditions found in adjacent strata of snow or bubbly and transparent ice. The ice in these dishes was examined, one at the end of four days, one on the seventh, and the third on the fourteenth day.

At the examination the dishes were set in a vessel of warm water which came up around the sides, and when the transparent zone at the sides and bottom was melted off, the resulting water was drained off after measured quantities for duplicate analyses had been secured by means of sterilized pipettes. The bubbly central portion was then allowed to melt, and duplicate samples of this were examined.

The following figures show the results :

Dish No. 1.	Dish No. 2.	Dish No. 3.
Outer clear zone contains in 1 c.c. 5,366 living bacteria.	Outer clear zone contains in 1 c.c. 1,808 living bacteria.	Outer clear zone contains in 1 c.c. 368 living bacteria.
Central bubbly zone contains in 1 c.c. 6,048 living bacteria.	Central bubbly zone contains in 1 c.c. 3,154 living bacteria.	Central bubbly zone contains in 1 c.c, 798 living bacteria.

It will thus be seen that the bubbly central portion, which when dropped as sodden snow into the bacterial fluid contained practically no bacteria at all, harbored, when examined together with the stratum next outside of it, into which a part of its air had been forced along the line of crystallization, a considerably larger number of living bacteria than the peripheral zone which contained almost no air-bubbles. This condition of affairs would seem to indicate that the bacteria had worked their way toward the air-bubbles during the short interval which elapsed between the introduction of the bubbles in the snow and the solidification of the mass by freezing.

Still these results could be explained by supposing that in some way the bacteria which lay among the radiating air bubbles, which had been forced out into the fluid by the freezing, were not killed in as great numbers as in the external transparent zone. We must see whether in fact these bacteria can travel through water toward air-bubbles. To test this several glass slides, with small concavities or pits in their upper surfaces, were sterilized, and the pit or cell nearly completely filled with sterilized water, in which had been uniformly diffused a small number of the fluorescent bacilli. The number was so small that the water in the cell remained perfectly transparent. Now a thin cover-glass was dropped over the cell in such a way as to leave one small bubble of air, the rest of the cell being completely filled with the bacteria-containing water. A rim of oil was now painted around the edge of the cover-glass, so that contact with the external air was completely shut off. Of course in these manipulations great care was taken that no external contamination should occur.

These slides were now set aside in a moderately warm place and examined after a few hours. In every case a distinct cloudy ring, like a halo, was readily seen close around the air-bubble, sometimes most marked at one side, while the remainder of the water in the cell was perfectly clear. An examination with the microscope showed this ring to be composed of large numbers of bacteria of the species originally introduced into the water. These apparently had made their way toward the bubble, close around which they were clustered.

But yet another possibility must be considered, namely, that the cloudy mass of bacteria around the air-bubble may not have come there from the surrounding water, but have found in this place conditions suitable for their proliferation and growth, and so been formed in large numbers on the spot.

Another set of slides was therefore prepared in exactly the same way, but, instead of being left in a warm place, they were put into a jar and sunk in a tub which contained a large quantity of melting ice and water, that is, at a temperature not much above freezing. Examination of these specimens after twenty four and forty-eight hours showed in a most marked manner, the halo of bacteria around the bubble in every case.

Now at this temperature, so far as we know, bacteria do not proliferate, so that it would seem to be true that in some cases at least bubbly ice contains more bacteria than adjacent transparent ice, because certain bacteria, owing to their need of air, tend to collect around air-bubbles which are present in water, and are caught there when freezing occurs.

It is not probable that this is the only reason, or applies in all cases. It is probable that in most cases the top snow-ice layer contains more bacteria because these are washed down upon the surface from the shores of the bodies of water on which the ice is forming, or come from the air.

Pengra has shown, as reported by Gardiner,[8] that in some cases at least the snow ice contains a considerably larger percentage of solid material than the clear ice below.

It is conceivable, also, that the physical conditions of the ice in which air-bubbles are very abundant and the crystallization irregular are such that less numbers of bacteria are killed in the freezing than in the more compact transparent ice.

Englemann,[16] in 1881, observed the tendency of certain bacteria to make their way in fluids to the edges of air-bubbles and to the vicinity of fluids containing oxygen, or plants which were developing it by their life-processes, and suggested this action of such bacteria as a delicate means of detecting the presence of the minutest quantities of oxygen in fluids.

The Different Species of Bacteria present in the Lake, Pond, and River Ice supplied to New York City.—A large number of different species of bacteria have been separated from the ice examined, in the form of pure cultures, and the life history of some of them has been traced in detail. But it is not within the scope of this article to enter into this part of the subject, because the work is not yet completed. No experiments have yet been made with a view of determining whether any of the species isolated are pathogenic.

It should be stated, however, as bearing directly upon our theme, that while the number of different species commonly occurring in the pond and lake ice is moderate, two or three being usually largely in excess, the number of species in the Hudson River ice is very great, more especially so in the ice formed near Albany. This is what would be expected when we remember what enormous numbers of different forms are always to be found in sewage and in sewage-contaminated streams or other bodies of water. The fluorescent bacillus appears to be more abundant in some of the pond ice, such as that from Ice Pond, than in the river ice.

It is not a little curious that, in the same block of ice,

different strata often show a marked difference in the species of bacteria which preponderate. So that we sometimes have in ice, not only, as above mentioned, a record of the temperature and other conditions of the air at the time the ice was forming, but also a memorandum, not less precise than that afforded by the fossils in geologic strata, of the flora which was most predominant in the water when it solidified. We are more fortunate than is the geologist, however, thanks to the method of biological analysis, in that by supplying the proper conditions of environment and nutrition, we can call our bacterial fossils back to life and make out the vital characters which, in their dormant state, are not revealed.

Summary.—Let us now review briefly the more prominent facts which this study has elicited. We have seen that by the biological analysis of water and of ice we are enabled to detect with great certainty the presence of bacteria, some species of which can give rise to serious disease, and that the chemical analysis alone does not suffice, in cases in which such organisms may be present, but that when we have determined the number of bacteria present in water or ice, a great deal of careful study of other conditions is still necessary in order to determine whether the water or ice is suitable for use or not.

We have seen that the popular impression that water purifies itself in freezing is only partly true. While some gross particles, and to a certain extent materials in solution may be largely removed, the bacteria, which are the most important, if not the sole agents in water deleterious to health, are only in part destroyed by the act of freezing. This partial purification from bacteria is not brought about by their expulsion from the water, but by the death of a varying proportion of them, which cannot survive this reduction of temperature. So that, if the bacterial contamination of the water is extreme, or is largely made up of the more hardy species, the ice formed from it, even though quite transparent, may still contain large numbers of the living germs.

Different species of bacteria possess differing degrees of vulnerability to the action of low temperatures. In some species nearly all the individuals are killed by prolonged freezing in water, while in other species a small proportion only is destroyed, and between these extremes are other species possessing intermediate degrees of resisting power.

Certain species of bacteria which are capable of producing serious and even fatal diseases in man—the bacillus of typhoid fever and the common bacterium of suppuration—are capable of resisting a prolonged exposure to a low temperature with the destruction of a part only of the individuals thus exposed.

The capacity of resisting a low temperature varies not only in the different species, but among the individuals of the same species, depending upon their condition of vitality when subjected to the deleterious influence. It varies also with the time of exposure to the cold and its intensity, and repeated freezings and thawings suffice to completely exterminate individuals and species which can successfully resist a steadily maintained low temperature. A persistent low temperature without freezing is more efficacious than when crystallization occurs.

While no absolute percentage of destruction can be given which will indicate the degree to which water containing bacteria usually purifies itself from them in the act of freezing, experimental data justify the belief that in ordinary natural waters there may be a purification of about ninety per cent.

The effect of freezing may in a general way be compared to that of filtration, but there is a very significant difference between them. By filtration the various species, dangerous and harmless, are eliminated with about equal efficiency, while in the purification by freezing the dangerous disease-producing species may be retained if they resist low temperatures, while more or less of the harmless forms may be destroyed. Freezing, therefore, acts as a selective filtration might, and may not free the water from all forms alike.

We have seen that the ice supplied to New York City comes from a series of naturally excellent lakes and ponds and from a great tidal river largely contaminated with sewage in its upper regions, and that by far the larger proportion of the ice comes from the latter source.

It has furthermore been shown that, while the conditions of the upper Hudson do not seem, during the ice-forming season, to be such as would favor purification from organic matter by oxidation, they do seem to be theoretically, and are shown to be practically, favorable to a considerable degree of spontaneous purification from bacteria by sedimentation, but that the limits and extent of this purification are yet to be made out.

Coming to the actual analyses of the ice from both the river and the lakes and ponds, we find a very much greater number of bacteria in the snow ice and in the very bubbly streaks than in the transparent ice, particularly in the snow ice on the top of the cakes. We find that while a part of this excess may be due to the washing down upon the surface of the ice from the shores of bacterial impurities, or their collection from the air, a not insignificant share is probably due, at least in the bubbly streaks, to the tendency which some forms of bacteria exhibit to collect in the vicinity of air-bubbles, and perhaps also to unknown physical conditions in the irregularly crystallized ice about these bubbles. Regarding the species of bacteria, we find that they are much more varied and abundant in the Hudson River ice than in that of the lakes and ponds, while in both there is a considerable proportion of the relatively harmless water bacteria.

We find that while the number of living bacteria varies greatly, not only in different parts of the same block of ice, but also in ice from different parts of the river and from the different lakes and ponds, the average number is considerably greater in ice from the Hudson River than in that from the lakes and ponds, even when ice taken from immediately below Albany is excluded from the estimate.

We have seen also that the average number of bacteria in ice from all sources taken together is far beyond the general standard which even a moderate degree of purity would allow.

But it is also evident that the transparent ice from some of the lake and pond sources presents in general a most admirable degree of freedom from bacteria.

Interpretation of Results.—We now stand at last face to face with the most difficult and at the same time the most important part of our study, namely, the interpretation of its results and the suggestion of the practical lessons which it teaches.

We must be guided in this task by the general considerations which were set forth at the commencement of this paper, when we were reviewing the practical value of the biological methods of water analysis.

We saw, then, that the simple statement that a given sample of water contained a large number of bacteria was without great significance, unless with it we have an account of the condition of the source of the water at the time of the collection of the sample, because a large proportion of the bacteria ordinarily present in natural waters are, so far as we yet know, relatively or absolutely harmless. We must know whether a considerable proportion of the bacteria present are the at least relatively harmless water bacteria, whether the source may possibly be contaminated with sewage, etc.

Now, exactly the same questions must be asked regarding the sources of our ice.

Considering first the ponds and lakes, we find that the natural situation and surroundings of most of them are excellent and that evident sources of contamination with excretory material can be largely excluded. Whether, in the case of Rockland Lake, the dwellings on the hillside near it might furnish sources of absolute danger in

the event of an outbreak of typhoid fever, or not, the writer is not prepared to say, and would leave this and all other detailed criticism of the sources of ice-supply to those who, having the public health in charge, can speak authoritatively on the matter.

The large number of bacteria present in the average Ice Pond ice may readily be accounted for by the proliferation of water bacteria and by the connection which this sheet of water has with a swamp, and experiment shows that a considerable number of these are actually forms which proliferate in water and which, so far as we know, do not produce disease in man.

As regards the ice from lakes and ponds, then, we may conclude that although the product from some of them contains a larger number of bacteria than is consistent with the highest standards of good sanitation, the conditions could be readily changed so as to render them quite unimpeachable, and in no case is there absolute reason, so far as the writer is aware, to fear contamination with forms which are known to be disease-producing; while in some cases, notably in the smaller ponds, the ice, so far as the analyses show, is well within the standard of absolute excellence.

The Hudson River ice stands, on the other hand, on an entirely different basis. Thoroughly contaminated with sewage at the upper part of the ice-fields, the water receives fresh accessions of bacterial impurities at various points near some of the ice-fields, which lie at a considerable distance from Albany.

Now, given ice from this source, in which the average number of bacteria per cubic centimetre is absolutely large, and a great degree of sewage pollution, we have to ask ourselves what is the actual danger which we have to fear from the use of the ice for drinking purposes.

A considerable number of the bacteria are undoubtedly the relatively or absolutely harmless species which may exist in any natural river or spring water, but a large number may, with equal certainty, be assumed to originate from animal excreta. Here, again, it is scarcely to be doubted, although not yet demonstrated, that a considerable proportion of the bacteria which exist in sewage coming from human and other animal excreta and the varied putrefying fluids which form a prominent ingredient in the waste of populous towns, may not be positively dangerous if taken into the body in moderate quantities in drinking-water, and so far as such bacteria go, it would seem to be largely a matter of taste on the part of the consumer whether he uses such material for drinking purposes without purification or not. On the other hand, in every large town, such as Albany, and in smaller towns in lesser degree, there is more or less constantly passing into the sewers in the excreta or other wastage a considerable number of bacteria which are the cause of serious disease, and here it ceases to be a matter of individual preference, because the interests of the public health are involved.

There are some varieties of diarrhœal disturbance, sometimes mild, sometimes severe, particularly affecting persons who are sensitive in the matter of ingesta, which often seem to depend upon impurities in the drinking-water and in ice. Whether these are occasioned by sewage or other bacteria, or by organic matter in the water or ice, or by both, is not yet fully decided, so that we may leave this class of cases out of view for the present.

Fortunately cholera and anthrax, both bacterial diseases transmittible by drinking-water, are not ordinarily present in the sewage of the region which we are studying, so that these diseases also, which must not be ignored by those having the public health in charge, do not fall within the scope of the present study. But there are two very common and very important bacterial diseases which are almost constantly present in large towns like Troy and Albany, and frequently so in villages like many of those which lie along the upper Hudson. These are typhoid fever and the diseases associated with acute suppuration and the so-called blood-poisoning from wounds or pyæmia.

Now, it is unfortunately true, as the above researches show, that the bacteria causing these two forms of disease are markedly resistant to the temperature at which ice forms. The most important of these, and the one to which the writer has paid most attention in these studies, is the typhoid bacillus.

The health statistics of Albany do not show the number of cases of typhoid fever which occur in the city during the various months, but only the number of deaths from the disease. The deaths from this disease in the city of Albany, for the details of which I am indebted to Dr. Balch, Secretary of the State Board of Health of New York, during the months in which the ice on the Hudson is ordinarily forming, that is, from December to March, are as follows: From December, 1883, to March, 1884, 20; from December, 1884, to March, 1885, 14; from December, 1885, to March, 1886, 16. That is, an average of about 16 each season. Now the number of deaths represents a varying number of actual cases of the disease, since the mortality is exceedingly variable. But if, in order to be on the safe side in estimating the actual number of cases, we take the highest rate of mortality which ordinarily occurs as thirty per cent., we find that the chances are, as judging from the statistics of the past three years, that there will be not far from fifty cases of typhoid fever whose excreta will pass directly into the Hudson River from Albany each year during the ice-forming season.

The writer is informed that in Albany, as in most American towns, both in the hospital and among private patients, there is no systematic disinfection of the typhoid discharges, which therefore enter the sewers with their myriads of bacteria in a living condition. That they are present in myriads and living in the discharges of typhoid fever patients is a well-known fact, which the writer has had abundant opportunity to observe in making cultures of them for diagnostic and other purposes.

Now, the bacteria of typhoid fever are capable, as has been shown by Frankland, by Wolfhügel and Riedel, and by Bolton, and confirmed by the writer, of living for a considerable period in water, and they may, according to Frankland and Wolfhügel and Riedel, even proliferate in the water, particularly if, as in sewage, there is organic matter present. We have seen from the above studies that when the bacteria of typhoid fever in the living condition become entangled in the ice and frozen a considerable proportion are destroyed, but also that a very significant remnant persists, living in the ice for long periods, and perfectly able, when thawed out and placed under favorable conditions, to go on growing and proliferating just as before their hibernation. Whether they may retain life indefinitely or not in ice we do not know, as one hundred and three days is the longest period during which they have been kept frozen.

Here, then, as it seems to the writer, is the positive source of danger in the use of the Hudson River ice directly for drinking purposes, without some form of purification, at least, until it can be ascertained at what distance below Albany, or other towns whose sewage drains into the river near the ice-fields, a safe degree of bacterial purification of the water from natural causes may have occurred.

It will undoubtedly be asked, if typhoid bacilli have been detected in the Hudson River ice. They have not, nor is it very probable that they will be, unless, possibly, by chance. For, in the first place, the search for particular species of bacteria in a large dilution, such as exists here, is an almost hopeless task, unless the species sought for possesses biological characters and peculiarities in its mode of growth on the culture media or in its appearance under the microscope which would render its detection among many other forms comparatively easy. Unfortunately this is not the case with the typhoid bacillus, whose identification can be complete only after a long series of various tests, among which, as is well known to bacteriologists, the growth in potatoes is the most

characteristic. In the second place, its growth on gelatin plates is slow, and mixed, as it must be in sewage, with many other species which rapidly fluidify the gelatin, the opportunity for the development of its colonies is not very favorable. It has been detected in several instances in water suspected to be the cause of outbreaks of typhoid fever,[17] but the conditions for its detection were more favorable than those which the Hudson River water presents with its large sewage dilution.

If we look, on the other hand, at the cases of typhoid fever as they are constantly occurring in New York and the adjacent towns where Hudson River ice is used, we do not find, and we should not expect to find, any marked excess of typhoid fever among those who habitually use ice for drinking purposes over those who do not, because the sanitary surroundings of the classes who do not habitually use ice for drinking purposes are so much less favorable, as a general rule, than those of the habitual ice-consumers, that other sources of infection, equally or even more efficient, would abundantly cover any revelation of the statistics.

If ice containing sewage contamination were the only means by which the typhoid-fever poison were conveyed from one individual to another, we might expect to find an indication of it in the statistics, but, unfortunately, it is not. We can only assume, as it seems to the writer, from what has been shown in these studies, that ice from some parts of the Hudson River, particularly near Albany, may contain, even in considerable numbers, living typhoid-fever bacilli, and so may furnish a means of propagating the disease. Whether this is a frequent or an infrequent occurrence we do not know. That it is not so important a factor in the transmission of the disease as to render the typhoid-fever statistics of New York worse than those of other towns whose residents use ice from cleaner sources, is certain.

But there is a considerable number of cases of typhoid fever, seen by every practising physician, in which the most painstaking examination of the sanitary surroundings of the victims and their personal contacts fails entirely to account for the occurrence of the disease. Some of these isolated cases of typhoid fever, whose origin is otherwise unaccountable, may well be due to the ingestion of typhoid bacilli from sewage-contaminated ice.

It should be remembered in considering this, as all other bacterial diseases, that the bacteria themselves are only one factor in determining the disease. There is to be taken into the account also the number of the bacteria, that is, the size of dose, and the condition of predisposition of the individual.

Now, unfortunately we know nothing about the number of typhoid bacilli which may be necessary to induce the disease in man, and we are equally ignorant concerning the nature of the predisposing conditions in the individual.

So that, if we sum up what we really know about the relations of Hudson River ice to typhoid fever, we can only say that the facts show that it is certain that the ice from some parts of the river must contain the bacteria of typhoid fever, and that these may be taken into the system with ice-water in a living condition. Whether the necessary relationship between the number of bacteria thus taken and the condition of predisposition of the individual occurs frequently or infrequently, or ever occurs at all, we cannot positively say, but the grave character of the disease should warn us against indifference in the matter, and such measures should be taken as will secure the consumer of ice against even the possibility of such infection.

Such considerations as these are apt to be met by those calling themselves, often somewhat ostentatiously, "common-sense people" by what may be called the "ancestor," or experience argument, which in this case would consist in saying that they and their fathers have used ice from the Hudson River all their lives, and have never suffered from typhoid fever. This view is one which ignores the necessary relationship between predisposition and determining cause, and the ever-increasing complexity of sanitary problems in large and growing towns. If the upper Hudson were still in the condition which prevailed when Hendrick Hudson made his exploratory voyage along its wellnigh tenantless shores, the ancestor argument might not be without a very modest value. But it should not be forgotten that with each new resident on the shores of the Hudson the increment of danger regularly increases.

With the bacteria of suppuration and pyæmia, the Staphylococcus pyogenes, the case is less serious. The contact of ice with wounds is not frequent, and when occurring may be guarded from possible ill-effects by antisepsis. The probability of infection in other ways from ice containing the staphylococcus is remote, but its presence would always suggest unpleasant and perhaps dangerous possibilities.

As to the pollution of the river water and the ice with this species, it is only necessary to recall how many cases of acute suppuration may be found at any time in a city of the size of Albany, and how much of the discharge is apt to find its way into the sewers without efficient disinfection, and to refer to the above experiments which show the resisting power of the bacteria to cold.

Practical Suggestions.—We now come to the practical measures which, as these studies seem to show, should be established in order to guard against a not only possible, but a very probable source of danger in the Hudson River ice. The writer is fully impressed, and wishes that those who may interest themselves in this matter should also be, with the great and important private and corporate interests which are involved in the supply and consumption of ice. Nor would the writer wish in any measure to suggest by these studies a curtailment in the consumption of ice, even for drinking purposes.

The great value of ice for actual consumption, especially in the summer months, in our city, among all classes, can hardly be overrated. The improper and inordinate use of ice for drinking purposes, which undoubtedly not infrequently occurs, is an abuse which belongs with other forms of intemperance and does not concern us here.

Now the measures which might be adopted in view of the present condition of affairs are of two kinds: First, such as would come under the supervision of those having the public health in charge; and second, those which belong in the province of the individual consumer.

In the first place, it would seem necessary that the State Board of Health, or some other authorized body, should have full control of the ice-harvesting fields, and, by a system of inspection not less strict than that which should exist in the care of the ordinary water-supply, determine which, if any, of the sources of ice-supply are so situated as to imperil the health of consumers of the ice. In view of what we know this would be comparatively simple in all cases except that of the Hudson River. Here it would be necessary to establish, by a most thorough scientific examination, the distances from all existing sources of sewage pollution at which it might be safely assumed that the water had freed itself from bacteria and other impurities sufficiently to form safe ice. It might in this way be possible to remove any chance of danger by permitting the questionable or bad ice to be sold only for cooling purposes, if such a classification is practicable, and thus not essentially interfere with the interests of the ice companies.

A compulsory system of disinfection of excreta in infectious diseases might be instituted here, as it is in other countries in which the purity of the water-supply is under constant supervision.

When we consider the measures which the individual consumer might adopt for the avoidance of possible danger from bad ice, it is evident, from what we have seen, that if he could be certain that his supply came only from

the lakes and ponds now used for this purpose, he would secure for himself, so far as the writer can judge, a fair degree of immunity from probable danger.

Remembering that the larger and more responsible ice companies do not, so far as the writer is aware, cut ice in the immediate vicinity of Albany, but at a considerable, and in the majority of cases at a great, distance below, the householder may eliminate to a certain extent his hazard by finding out, as accurately as possible, just what part of the river his ice comes from.

Whatever the source of ice-supply, however, the large excess in bacterial content which, in almost all cases, the snow-layer harbors over that of the transparent or sparsely bubbly ice, would render imperative the avoidance of the snow-layer for any but cooling purposes. But it should still be borne in mind that perfectly transparent ice may harbor very large numbers of living bacteria, if formed from water in which they were abundant.

A variety of devices can be adopted in the use of ice for the cooling of drinking-water, such as pitchers which contain separate receptacles for the ice, the cooling of the water in refrigerators, etc., which the ingenuity of the individual might suggest.

Or recourse may be had to artificial ice made from pure water, which, as a great deal of experience in the matter has shown, may be furnished at a cost not very greatly exceeding that at which the natural ice is delivered.

This is already done in some of the Continental cities. Thus in Berlin, Germany, a company exists which furnishes artificial ice made from distilled water, which, as would be expected, is almost absolutely free from contamination.

Such water as is furnished by the Hygeia Distilled Water Company in New York would, if artificially frozen, make a most admirable and safe substitute for the natural ice.

The writer must be content, in this series of pioneer studies on the impurities of ice, with having, by experimental means, endeavored to give definiteness and precision, not only to the problem in general, but to the detailed questions which arise in connection with the ice-supply of one particular town.

It would appear that we now know with tolerable certainty just what series of questions are to be answered, and investigations made, in order to decide upon the safety of any given source of ice-supply. But these detailed investigations can only be made under the sanction and direction of the public authorities.

It is unfortunate that a certain amount of perhaps entirely unjust opprobrium is now attached to all of the Hudson River ice, when it should perhaps belong only to that harvested in particular regions. It would therefore seem to the writer that it is greatly to the interest of the ice companies, as well as the public, that the State health authorities should take the matter of detailed examination of the Hudson River ice-fields at once in charge.

In conclusion, the writer wishes to express his sincere hope that this study may not be looked upon in a sensational light, nor regarded as a polemic against ice companies and dealers, or against the free and wonted use of ice, the incalculable usefulness of which is beyond question. A most thorough personal examination of the ice-harvesting and the practice and purpose of the more responsible dealers, lead to no other conclusion than that they are as desirous as could reasonably be expected of them to furnish a clean and pure product to the market, and, so far as facts have hitherto instructed them, have apparently done so. But in the clear light which the new methods of science throw upon the whole subject of important ice impurities, it seems necessary that a sweeping reform, in some respects, should speedily be brought about. This long and expensive series of researches has been carried out in the hope that in the light of its results the rapidly developing discipline of "preventive medicine" might find a plan of curtailing, in some degree, the number of annual victims to preventible disease.

THE TREATMENT OF RUPTURED AND DIVIDED TENDONS.[1]

BY C. H. WILKIN, M.D.,

NEW YORK.

MR. CHAIRMAN AND GENTLEMEN: At the request of your honorable chairman, I present to you this short paper, and a few cases which will serve to illustrate the results of suture of tendons.

I am disappointed in not being able to present some case operated upon by myself, but the fact that I have had only four days' notice in which to prepare this and collect the cases, and that those operated upon by me were unwilling to come here, I trust, will be sufficient excuse for this shortcoming. Those that I will present were done at the Chambers Street Hospital under my direction, by a very competent house staff, and will, in a measure, serve to illustrate any special points in the treatment. The title of this paper is "The Rupture and Division of Tendons and their Treatment."

For convenience these injuries, like fractures, are divided into *simple* and *compound*. The *simple* being those with no external wound or atmospheric communication, and the compound being those in which such external communication exists.

The first class are important, because of the deformity and disability that are likely to ensue; and the second, because, in addition to these, we have often to deal with a grade of inflammation that may not only destroy the usefulness of the part involved, but in extreme cases may end in the death of the patient.

These injuries occur so frequently and are so often causes of *permanent* deformity and disability, that it is quite important that the best method for their relief should be generally understood. Probably no tissue in the body, with the exception of the delicately constructed serous membranes, is so prone to inflammation as the synovial membranes lining the joints, and that forming the sheaths of tendons.

This fact will account in a great measure for many of the bad results following injuries of this kind. The severity of the inflammatory process which sometimes follows such an injury is due in a measure to the extent of surface involved, for it is estimated that, on an average, tendinous sheaths, of which that of the finger is an example, presents a surface when dissected and spread out

[1] Read before the Surgical Section of the New York Academy of Medicine, March 14, 1887.

of from ten to twenty square inches. The fact that the inner surface of the sheath is constantly moistened with a fluid, the synovia, which is especially liable to fermentation and decomposition when exposed to atmospheric influence, will be sufficient to account for the frequency of inflammation and suppuration after injuries of this kind.

From the *manner* in which inflammation commences in these wounds, as it often does even now in the days of antiseptic surgery, it seems that it must rest in the fact that the antisepsis is imperfect.

tendon a focus of inflammation has started, as indicated by a point of tenderness, heat, swelling, pain, and redness. In looking for a cause for this, it appears that the pump-like action of the divided tendon, working in its sheath, draws the material containing the germs into the sheath up as far as the original retraction takes place, or else that some of this material came in contact with the tendon at the time of the injury, and was then carried by it up to this point, or that it was pressed up by the application of the Esmarch bandage.

It is quite clearly demonstrated that divided tendons

No.	Cause.	Tendons.	Suture.	Inflammation.	Anæsthetic.	Results.
1	Glass.	Flexor carpi radialis; palmaris longus; flexor sublimis.	Catgut.	Cellulitis.	Ether.	Motion good; secondary union; three weeks.
2	Knife.	Ligamentum patellæ.	Catgut.	No inflammation.	Ether.	Motion perfect; primary union; five weeks.
3	Glass.	Flexor carpi ulnaris; flexor sublimis digitorum.	Catgut.	Inflammation.	Ether.	Discharged cured; seven weeks.
4	Direct violence; simple.	Quadriceps; extensor tendon.	Catgut.	Superficial suppuration.	Ether.	One month; perfect motion and union.
5	Unknown.	Flexor sublimis digitorum.	.....	No inflammation.	Ether.	Moderate use; one month.
6	Glass.	Extensor tendon of thumb.	Catgut.	Cellulitis.	Cocaine.	Motion good; secondary union; three weeks.
7	Glass.	Extensor of ring finger.	Catgut.	No inflammation.	Cocaine.	Motion perfect; primary union; two weeks.
8	Glass.	Extensor of index finger.	Silkworm-gut.	No inflammation.	Cocaine.	Motion perfect; primary union; two weeks.
9	Glass.	Extensor secundi; internodii pollicis.	Catgut.	Cellulitis.	Cocaine.	Motion good; secondary union; six weeks.
10	Glass.	All flexors of fingers; flexor carpi ulnaris; ulnar and median nerves.	Catgut.	Cellulitis.	Ether.	Motion good; sensation returned; secondary union; six weeks.
11	Glass.	Flexor carpi ulnaris; ulnar nerve.	Catgut.	No inflammation.	Cocaine.	Motion perfect; secondary union; anæsthesia; two weeks.
12	Knife.	Two flexors of index finger.	Catgut.	No inflammation.	Cocaine.	Motion good; primary union; two months.
13	Glass.	Extensor tendons of first, second, and third fingers.	Catgut.	No inflammation.	Cocaine.	Motion perfect; primary union; three weeks.
14	Glass.	Superficial flexors of third, fourth, and fifth fingers; in forearm.	Catgut.	No inflammation.	Ether.	Motion good; primary union; three weeks.
15	Glass.	Extensors of thumb, all.	Catgut.	Cellulitis.	Cocaine.	Motion fair, two weeks; secondary union; perfect motion, six months.
16	Razor.	All extensors of fingers and thumb.	No suture; splints used.	Cellulitis.	None.	Motion in fingers, five weeks; fair; motion in thumb, none.
17	Knife.	Belly of extensor carpi radialis.	Catgut.	No inflammation.	None.	Motion good; primary union; three weeks.
18	Glass.	Superficial and deep flexors of index and middle fingers.	Silk and catgut.	Cellulitis.	Ether.	Fingers dropped back, eleven days; slight flexion, seven weeks.
19	Glass.	Extensor tendon of middle finger.	Silkworm-gut.	No inflammation.	Cocaine.	Motion perfect; primary union; three weeks.
20	Razor.	Knee-joint opened; quadriceps; extensor tendon.	One catgut in muscle, four silkworm-gut sutures in tendon.	No inflammation.	Ether.	Motion good; primary union; two weeks.
21	Glass.	Extensor carpi radialis longior.	Catgut.	No inflammation.	Ether.	Discharged cured; primary union; moderate motion; six weeks.
22	Razor.	Deep and superficial flexors of ring finger.	Catgut.	Tenosynovitis, cellulitis.	Ether.	Discharged cured; six weeks.
23	Knife.	Tendo-Achillis.	Catgut.	No inflammation.	Ether.	Motion perfect; primary union; five weeks.
24	Glass.	All extensors on dorsum of wrist except those of thumb.	Double silk.	Cellulitis.	Ether.	Motion perfect; five weeks; secondary union.
25	Glass.	Six flexor tendons at wrist; ulnar artery; ulnar nerve.	Catgut.	Cellulitis.	Ether.	No union, two weeks; full motion, one year.
26	Glass.	Extensor tendons of ring and little fingers.	Catgut.	Inflammation.	Ether.	Secondary union; result not given.
27	Glass.	Flexor of fifth finger.	Catgut.	Inflammation.	Ether.	No union in tendon; secondary union in wound.
28	Glass.	Flexors of index finger.	Old wound tendons dissected up and sutured; catgut.	Inflammation.	Ether.	No power of flexion; primary union in wound.
29	Glass.	Superficial flexor tendons of hand; palmaris longus.	Catgut.	Inflammation.	Ether.	Discharged cured; motion not stated.
30	Razor.	Superficial and deep flexors of hand.	Tore sutures; suicidal mania; catgut.	No cellulitis.	Ether.	Limited motion; one month.

We have been struck with the fact that the beginning of the inflammation is not directly in the wound itself, but commences in the sheath of the tendon at a point some distance from the point of injury. For instance, a tendon is divided in the palm of the hand from an incised wound—this is thoroughly cleansed, washed with soap and water, and the wound and surroundings irrigated with bichloride solution, 1 to 1,000, and then by the usual means the separated ends of the tendon are brought together with sutures (catgut being that generally employed), and the external wound is sutured and dressed antiseptically. In a few days it is noticed that farther up the sheath of the

in an open wound will rarely unite if left to themselves, and that something must necessarily be done if a good result be desired.

We cannot depend upon the ordinary plans of treatment employed in the simple forms.

Union in the simple and compound forms takes place as differently as does union in simple and compound fractures. The process of repair in the simple form consists mainly in a low grade of inflammatory action, in which the interspace is filled up with plastic matter which soon becomes organized into a tendinous band. This takes place in from six to twenty-one days, depending

upon the size, situation, and amount of separation. The process of repair in the compound variety takes place if only a punctured wound or subcutaneous division be present, usually as in the simple form. Generally, however, the union is by granulation, and with involvement of much of the surrounding tissue, which becomes matted down and bound with the tendon into the cicatrix.

The process of repair in suturing of tendons, as done under all antiseptic precautions, is reduced practically to the same point as in the simple subcutaneous rupture, and shows even better results, because of the closer approximation of the divided ends.

In the treatment of these injuries several questions present themselves. In the simple form, or rupture without atmospheric communication, is it necessary, or are we justified in opening the sheaths and suturing the tendon? Do the results of the rest and position plan of treatment, as accomplished by splints, etc., indicate that it is necessary to do this?

Then, in the compound form, is it not possible that the suturing, etc., can be done with such thorough antisepsis that the inflammatory trouble may be avoided? In simple rupture almost all of the authorities seem to agree that rest and position are sufficient. Yet it would seem that a better result, and certainly closer approximation, could be obtained by the use of the suture.

In the compound variety the point of inflammation would suggest the plan of treatment of a more thorough irrigation of the sheath of the tendon and of the adjacent tissues. A small English catheter with a syringe attachment will accomplish this, the solution employed being bichloride, 1 to 1,000, except in the quadriceps extensor tendon, which opens into the knee-joint, then 1 to 5,000 should be used.

The question comes up of what is the best material for uniting the divided tendons? Various substances have been employed, namely, catgut, horsehair, silk, silver wire, and, finally, the so-called silkworm-gut.

Probably catgut is more frequently employed than any of these. Some object to its use because they say it melts down too quickly before union can take place, others think it is the source of inflammation in the sheath from the decomposition which must necessarily take place for its absorption.

Silver wire is recommended by many in preference to catgut. We have recently used the silkworm-gut for this purpose at the Chambers Street Hospital, and it seems to be the best material yet used for this purpose, from the fact that it is not absorbed too quickly, if at all, and is non-irritating.

I am able to present the accompanying statistics, through the assistance of Dr. Paul E. Tiemann, of the Chambers Street Hospital, and Dr. C. F. Stokes, late of Bellevue Hospital, and Dr. J. L. Adams, of the New York Hospital. From the imperfect records to be found in these hospitals, with the exception of the Chambers Street Hospital, it was almost impossible to get any definite idea of the results in these cases.

The plan of treatment recommended in the compound form is, first, the thorough cleansing of the part and irrigation of the sheath with the catheter, the use of cocaine and the Esmarch bandage, and the use of the silkworm-gut suture, two sutures being necessary in the average tendon, one being carried transversely through the tendon, and the other antero-posteriorly.

Treatment of Cystic Tumors of the Ovary by Electrolysis.—Dr. F. Semeleder has published a memoir read by him before the Academy of Medicine of Mexico, entitled "Forty-five Cases of Ovarian and Parovarian Cysts treated by Electrolysis." The results obtained were very satisfactory, and the author believes that a trial should be made of this method in all cases before resorting to operative measures.

CASE OF DERMATITIS HERPETIFORMIS RESEMBLING ERYTHEMA MULTIFORME.

By LOUIS A. DUHRING, M.D.,

Professor of Skin Diseases in the University of Pennsylvania.

In January, 1884, I was requested by Dr. Mitchell, of Elkton, Md., to see a case of chronic cutaneous disease, exhibiting peculiarities which made the diagnosis difficult. The patient was a man seventy years of age, a lawyer by profession, neurotic, and in poor general health.

The disease had existed a year or longer, and was characterized by a profuse, multiform, general eruption, with violent itching and burning. None of the various plans of treatment previously employed had afforded any relief.

From his physician I further learned that the lesions of the skin had varied in character from time to time, having been sometimes vesicular, and on other occasions erythematous; while more frequently there had existed a combination of these elementary forms. Itching had always been a marked feature.

When I first saw the case the whole general surface was the seat of an abundant, diffuse eruption, characterized by ill-defined, marginate, annular, and circinate erythematous patches, upon which, in many places, were more or less well-formed, variously sized and shaped papulo-vesicular and vesicular lesions. The skin showed, moreover, signs of subacute and chronic inflammation, in the form of thickening, pigmentation, excoriations, and blood-crusts, as well as lesions in all stages of development. The erythematous patches predominated, and had coalesced to such an extent that their outline was only in places defined, but everywhere could be seen a disposition to form marginate shapes, as in erythema multiforme. The patches were on a level with the surrounding skin or were slightly elevated, and were acutely congested and infiltrated with inflammatory products, partly plastic and partly serous in nature. In color they were bright-red or violaceous-red, according to their age, and were mottled, owing largely to the fact of their having run together. The whole general surface, but especially the trunk, was affected in this manner; in addition to which, seated upon these patches were, for the most part, flat, small and large papulo-vesicular and vesicular lesions, here and there well defined, elsewhere imperfectly developed or abortive. The picture, as might be imagined, suggested an extensive diffuse or generalized "chronic" erythema multiforme, with papulo-erythemata, papulo-vesicules, and vesicules. The herpetic element was striking, as shown by the grouping and by the marginate peripheral extension of the process. Here and there the lesions were grouped in an ill-defined circinate form, as in tinea circinata, some of the patches being small, others large. In most localities they were so multiform and had merged one with another so extensively that the elementary characters were to be noted only on close inspection. Scratch-marks, excoriations, and small and large blood-crusts were everywhere present, testifying to the intense itching which had been experienced. The patient stated that this had always been a distressing symptom, was subject to exacerbations, and that it was always at its height during the time a new crop of lesions were developing, occupying usually about a week. The pigmentation was of a dirty-yellowish, muddy, or dusky hue, and was both localized and general. It called to mind that seen in the later stages of extensive pityriasis rosea of the trunk.

From a diagnostic stand-point the eruption resembled diffuse, aggravated erythema multiforme of long standing. Herpes iris was not suggested, the erythematous element prevailing. It possessed a history, however, as well as features which precluded it from being classed here. The chronicity of the process, the tendency to repeated relapses, the obstinacy of the disease, together with the violent itching and burning, would not permit it to be considered as a case of this disease, at least as

this affection is now defined. At the same time, I would state that the case possessed certain features in common with this disease, and certainly bore more resemblance to it than to any other well known cutaneous disease. And this brings me to a question that has presented itself on several occasions in studying dermatitis herpetiformis, namely, where (in certain cases) shall the line be drawn separating this disease from other well-defined diseases? Shall, for example, the case I have just cited be regarded as erythema multiforme or shall it be grouped under the title dermatitis herpetiformis, where I have placed it? Shall a new definition be framed for erythema multiforme, to include also a *chronic* process, in order that this and similar cases may be grouped under this title; or shall we regard such instances as too far removed from erythema multiforme to be classed here, and relegate them to another group? The line separating one disease of the skin from another in some instances is ill-defined, and there are cases occasionally encountered which may as properly be classified under one head as another.

Instances of the kind are met with from time to time with eczema and psoriasis, pityriasis rubra and psoriasis, and, to pass to more chronic forms of inflammation, with lupus erythematosus and lupus vulgaris. They exhibit symptoms common to both diseases and defy precise, schematic classification.

The case under discussion, however, I think, may more properly be regarded as an example of the erythematous variety of dermatitis herpetiformis than of erythema multiforme, especially if we take into consideration the history of the disease. In some respects it resembles that reported by Jarisch as "herpes iris," and referred to by me in the article entitled "Preliminary Note on the Relation of Dermatitis Herpetiformis to Herpes Gestationis and other similar Forms of Disease" (*Medical News*, November 22, 1884).

I saw the patient on several occasions during the subsequent six months, his condition having somewhat improved, although he still suffered much. It is not necessary to enumerate the various internal and external remedies that were employed; suffice it to say that they were such as might have been prescribed for chronic universal erythematous eczema. Notwithstanding the treatment the disease persisted, and relapses, though milder in form, occurred as before.

I report the case, because it is interesting as portraying an unusual manifestation of the disease, namely, one bearing a resemblance to erythema multiforme. In a former paper I alluded to the possible relationship between these two diseases, and this case would go to show that the causes at work in these diseases are capable of giving rise to similar cutaneous lesions. Additional clinical information, however, is needed concerning unusual forms of both diseases before definite views can be expressed, and it is to be hoped that the experience on this point of other dermatologists will be forthcoming.

The South African Ladies are so modest that they will seldom permit a physical examination of the chest to be made by a male physician. There would seem to be a wide field in that country for female practitioners.

A Convenient Vaginal Douche.—Dr. Lefour, of Bordeaux, describes an apparatus designed by himself for use in antiseptic douching of the vagina. It consists simply of two metallic tubes passing through a cork, which may be fitted in any bottle. One tube passes just through the cork, and the other is long enough to reach to the bottom of an ordinary pint bottle. The latter serves for the admission of air, while the former is the delivery tube. The bottle is filled with the antiseptic fluid, the rubber cork through which the tubes pass is fitted into its neck, and it is then inverted and the liquid flows out. A rubber tube with vaginal nozzle is fastened to the metal delivery tube.

Clinical Department.

EXTRA UTERINE PREGNANCY, WITH PERITONITIS—RECOVERY.

Dr. N. P. Warner, of New Woodstock, N. J., reports the following case: Mrs. C.——, aged forty, married ten years, gave an incomplete history of a miscarriage at second month, accompanied by pelvic inflammation, occurring about four years ago. Aside from this she was never pregnant. Menstruated last on September 15, 1885, and at the date of my first visit, November 12th, she supposed herself pregnant. She was then suffering from intense pain in the region of the right ovary, which came on suddenly as she was rising from her bed. External examination showed a slight prominence over the seat of pain, and some distention and tenderness of entire abdomen. Hypodermic injection of morphia and hot fomentation soon afforded relief.

Ten days after the first attack, as the patient was using the vessel, there was a return of the pain, although not so severe as at first. At this time a vaginal examination was made, which, however, was not very thorough, owing to the tenderness of the parts.

November 16th, patient had a slight return of pain, accompanied by a rather free discharge of blood from vagina, the discharge lasting a few hours.

December 7th, while using vessel for relief of bladder, she was again seized with cramping pains in right of abdomen.

During the following month the patient experienced some pain and soreness in the right iliac region, and once during that time there had been a flow of blood from the vagina.

On December 7th a more thorough examination was made. The os uteri was enlarged, and presented the soft, velvety feeling of the pregnant womb. There was a slight varicose condition of the lower portion of the vagina, the mucous membrane of which was of the lilac color so peculiar to the pregnant state.

Bimanual examination showed the uterus to be pushed over to the left of the pelvis by a tumor which occupied the pelvic cavity to the right. The tumor presented a smooth surface, was not very sensitive to pressure, and seemed attached to, but not a part of, the uterus. It gave an indistinct sense of fluctuation. There had been morning sickness and the breasts were enlarged and painful. Dr. Warner believed that he had to deal with an extra-uterine pregnancy, and he told the patient that he desired to make another examination after an interval of a few days, as there was still considerable tenderness about the abdomen and pelvis. She would not then consent to further examination, and the writer saw no more of the case until December 20th, when he was summoned in great haste at about 6 A.M. On his arrival he was informed that the patient, on arising in the morning to relieve the bladder, had been suddenly seized with sharp pain in lower and right side of the abdomen. She had been lifted back to her bed, and she now lay there on the right side, with thighs flexed and body bent forward, moaning with pain and nearly unconscious. The face was very pale, and gave indication of extreme suffering. The surface of the body was cold and clammy. Radial pulse hardly perceptible. Rupture of sac formed by extra-uterine pregnancy was suspected, and morphine and brandy were given hypodermically, and hot applications were made to the extremities and along the spine. The patient was unable to swallow, being in a semi-comatose condition. There was vomiting at short intervals. Respiration was rapid and feeble. The abdomen was distended and tympanitic, and the tumor in the right inguinal region was quite perceptible above Poupart's ligament. At the end of two hours the pulse became stronger, and was then 146 per minute; axillary temperature, 97°. The extremities and surface of the body

indicated an improved circulation, and at 10 A.M. the patient was gradually 'rallying from the collapse and complained of intense pain and tenderness over entire abdomen. Warm cloths were applied to abdomen, and gave some relief to the patient. The following morning the condition was but slightly changed. The urine was passed naturally. In the afternoon the patient was suffering extreme pain, and showed symptoms of collapse again ; there was occasional vomiting of a dark, grumous material. Morphine, veratrum viride, and brandy were given hypodermically. The entire abdomen was painted with tincture of iodine. At 6 P.M.: Temperature, 102° F.; pulse, 140, and more steady ; the general appearance was somewhat improved. The next day there was occasional vomiting, but most of the food was retained. The abdomen was painted again with iodine. Patient felt comfortable.

The abdominal tenderness, pain, and distention gradually subsided, and improvement was now steady. With the subsidence of the abdominal distention the tumor could be readily mapped out, and was unmistakably increasing in size, and now extended above the anterior superior spinous process of the ilium, and a little to the left of the median line. It was not painful to the touch, except at the side adjoining the uterus. The uterus and tumor were readily distinguished as separate bodies. The os uteri occupied the anterior and left of the vagina, and the fundus could be felt above the pubis and to the left of the median line. The probe showed the uterine cavity to be two and a half inches in length. The tumor was slightly movable, rather tense, and gave, as before, an indistinct sense of fluctuation. The surface of tumor above was smooth and oval, but examination per vagina and rectum showed an uneven, rather unyielding, but not hard surface.

At this time, January 5th, Dr. I. N. Goff saw the case in consultation, and fully concurred in the diagnosis. A long hypodermic needle was passed through the vaginal vault into the tumor, and on withdrawing the piston the syringe filled with bright blood. A fine needle was then attached to the syringe, and passed into the tumor at its most prominent point through the abdominal walls. The patient was very emaciated, and the abdominal walls quite thin. On withdrawing the piston the syringe this time filled with light-colored liquid, which was supposed to be amniotic. No evidences of decomposition were found in the fluids removed by the hypodermic needle. In examining the blood removed through the vagina a formation was discovered which very closely resembled a placental villus. The diagnosis of extra-uterine pregnancy being established and the fœtus being still living, an injection of twenty drops of tincture of iodine was made into the tumor, with a hypodermic syringe, through the roof of the vagina. No very noticeable effect followed immediately upon the injection of the iodine, although it seemed as though, for a few days, there was a slight diminution in the size of the tumor.

One week after the injection of the iodine an exploratory puncture was made with the hypodermic syringe ; and a dark-colored decomposing fluid removed from the tumor. Dr. Goff again saw the case at this time. The patient was anæsthetized and a median-sized trocar was passed into the tumor through the vaginal vault. Immediately there was a discharge of dark, thick, and very offensive fluid. The cannula, being provided with a flange, was left in the tumor for forty-eight hours, during which time the discharge continued, but not freely. After further consultation with Dr. Goff, it was determined to enlarge the opening made by the trocar and endeavor to remove the contents of the sac. On February 1st, assisted by Drs. Goff and Potter, Dr. Warner undertook the operation. The patient was anæsthetized and placed in the lithotomy position. The bladder having been emptied, a moderate-sized ring-pessary was introduced to aid in distending the upper part of the vagina, and the perineum was well drawn back by a Sims speculum. A director was passed into the sac through the opening made by the trochar, and along this a probe-pointed bistoury was passed and the opening was slightly enlarged by cutting toward the right side and backward. By means of dressing-forceps and a uterine dilator the opening was enlarged until the index-finger could be passed into the sac. The distance from the roof of the vagina to the entrance into the sac was about one and a half inches. In an attempt made to enlarge the opening so as to introduce two fingers through it, the bladder was wounded, or, rather, torn into, although but little force was being used at the time. On account of the distance from vagina to entrance of sac and the injury to the bladder, it was thought advisable to make no further attempt at that time to remove the fœtus entire. A large drainage-tube was placed in the sac, which was thoroughly cleansed with injections of tepid carbolic-acid water.

The patient rallied well from the anæsthetic. Two days afterward one of the lower extremities of a decomposing fœtus was removed, and within a week the remainder of the fœtus was taken away in pieces. The parts removed corresponded in size to a fœtus of about twelve to fourteen weeks. A catheter was kept in the bladder for two weeks, at the end of which time the urine passed naturally and the injury to that organ had entirely healed.

The sac was syringed out daily with a weak solution of carbolic acid. The discharge, at first dark and offensive, gradually became more purulent. Patient improved steadily. By March 1st the tumor was about the size of a goose's egg, and discharged only a small amount of healthy pus. Some trouble was experienced in keeping the drainage-tube in place, but this was overcome by attaching a button to the vaginal portion, which rested on the perineum and prevented the tube from dropping out. The patient menstruated on March 14th, for the first time since September 15th. For a few months menstruation was accompanied by severe pain in the right ovarian region, but at the present time, one year after the removal of the fœtus, the patient says that menstruation is no more painful than before her sickness, and she is apparently in the enjoyment of perfect health.

CARLSBAD WATERS IN THE TREATMENT OF GOUT AND BILIOUSNESS.

Dr. J. B. Potsdamer, of Philadelphia, reports the following cases: Mr. B. J——, aged sixty-nine, had an attack of renal colic about twenty-two years ago. Oxalate crystals appeared in the urine. For a time his life was despaired of. Fifteen years ago he began to grow stouter, and had periods of depression. He consulted a physician at that time, who advised horseback exercise, otherwise serious results might follow. This instruction was not carried out. Eleven years ago, while being treated for a Colles fracture of the left side, he had an attack of inflammatory rheumatism, confined to the right shoulder-joint. Shortly after this he had another attack of renal colic, not as severe as the first one. Since 1860 he has had occasional attacks of muscular rheumatism, at times quite severe. In the early part of last year he began to complain of pain in the thumbs, which were swollen. He had pain in the toes, but not so marked. The pain in the thumbs kept him awake at night. He takes very little exercise. Diagnosis: Gout. He was put on a course of iodide of potassium and the wine of colchicum seed, without beneficial results, although pursued for a long time. The salicylates were then tried, with the same result. Both the above methods were pursued in conjunction with a regulated diet. He was then placed on Carlsbad waters, the Sprudel being used. He drank three or four wineglassfuls a day, the water always being heated first. Beneficial results were noticed before beginning the second bottle, as the patient was able to

sleep at night. Improvement continued, and after six bottles had been used the pain was gone and the swelling disappeared. At the present writing, six weeks after this treatment was begun, the patient is perfectly well, having used but ten bottles of the water. The only restriction placed upon Mr. B. J——, while drinking the Carlsbad waters, was that he was not to drink any malt, and very little of spirituous, liquors. This he did not carry out, as he drank about a glass of beer a day.

Mrs. S. B——, aged forty-five, of full habit. Has had frequent attacks of biliousness. She was first seen in the early part of last fall. Symptoms as follows: Complexion muddy; tongue coated with yellowish fur; bitter taste in the mouth; appetite poor; bowels constipated; some dizziness. Her feet are somewhat swollen. Small doses of calomel were given, followed by a saline purge. Bitter tonics were then administered. Jalap, fifteen grains, and cream of tartar, one ounce, were given about every four days, to keep the bowels open and to diminish the swelling of the feet. The patient improved, but about six weeks later the writer was again sent for, and found a recurrence of the above symptoms. On physical examination the liver was found to be considerably enlarged. Carlsbad Sprudel water was ordered, in wineglassful doses, four times a day, *to be taken cold.* The patient soon began to improve. After taking five bottles, she is now well. The swelling of the feet has disappeared, and the bowels are regular.

Mr. S. H——, aged forty, rather plethoric, exhibited symptoms similar to those of Mrs. B——, but the feet were not swollen, and the liver not enlarged. The same treatment was pursued, with a regulated diet; and the patient recovered after taking three bottles.

Progress of Medical Science.

The Injurious Effects of Blisters.—Dr. Wyss, of Geneva, has published a warning against the use of blisters. He says that, although devoid of real remedial properties, they are still daily prescribed, perhaps more with the view of sustaining the hopes and confidence of the patient, and of gaining time for the natural process of recovery, than in the expectation of actual benefit. The long experience of an extensive practice leads him to consider blisters an unnecessary cruelty to the patients, which ought entirely to be discarded. He has employed blisters in the treatment of pneumonia, pleurisy, sciatica, and other diseases, but failed in ever observing the slightest benefit from their use. On the contrary, he found them more or less injurious. He thinks that blisters disturb the sleep of the patient in want of restorative rest; they impair in many irritable patients the urinary organs, and they frequently bring on obstinate cutaneous eruptions. Moreover, they cause actual harm by almost invariably increasing the fever in already feverish patients, and may thus seriously affect the general condition.—*Der Fortschritt*, January 5, 1887.

Antipyrin in Migraine.—Dr. Sprimon has stated in a Russian medical journal, quoted in the *London Medical Record*, January 15, 1887, that he uses antipyrin in all cases of hemicrania, and, as a rule, obtains excellent results. Given at the height of a fit, the drug only partially relieves pain, but does not shorten the duration of symptoms (especially when the patient remains on his legs all the while). But when administered during the period of prodromal phenomena, antipyrin almost invariably cuts short the paroxysm within an hour, and allows the patient to immediately resume his occupations. The dose required is one scruple. In delicate persons, or in those liable to giddiness, it is better to divide the dose in two parts and to give the second portion (if necessary) about half an hour after the first. In the *Centralblatt für klinische Medizin*, No. 45, 1886, Dr. Ungar also states that antipyrin, given in the dose of sixteen to twenty-four grains in the beginning of a paroxysm, acts better than any other symptomatic means used for the affection in question. In some cases, however, the drug (like salicylate of soda) remains inactive. According to the *London Record* of April 15, 1886, Professors M. A. Khomïakoff and I. M. Lvoff, of Kazan, were the first to recommend antipyrin as an excellent means for hemicrania, as well as for headache generally. This would appear to antedate the first publication of Dr. John B. White, of this city, in the *Medical News* of July 10, 1886. But as Dr. White had used and recommended antipyrin in various forms of headache for some two years before that time (The Medical Record, September 11, 1886), the credit of priority over the Russian physicians probably belongs to him. In any event, antipyrin has now received so many indorsements from different medical men that it may be placed once for all on the list of symptomatic palliatives in most forms of headache.

The Action of Pyridine on the Function of Respiration.—In health and in disease (phthisis, pleurisy, chlorosis, etc.) inhalations of pyridine have the effect of diminishing the quantity of air respired in a fixed period of time. Notwithstanding this, the feeling of need of air diminishes. According to Dr. B. Silva, the respiratory curve shows that in the healthy man pyridine produces at first an expiratory dyspnœa; the respiration then becomes less frequent, irregular, preventing true periods and sometimes long intervals of apnœa. After the inhalation the respiration remains less frequent and less full, with occasional deep inspirations. Sometimes sleep intervenes, and the periodic respiration is then more evident. The inhalation always causes abundant salivation, preceded by a bitter taste in the mouth and roughness of the throat, with constant desire to spit; the nose also runs. The respiratory curves obtained by exciting the nostrils by the faradic current are very similar to those obtained by pyridine. The nose runs, there is salivation, expiratory arrest, the respiration is disturbed and becomes sometimes periodic, and, lastly, after the excitement has ceased, there are the occasional deep inspirations and those periods of apnœa as seen after the inhalation of pyridine. But sleep and the sense of less need of air are wanting. The author therefore believes that pyridine acts on the respiratory centre by means of the trigeminus chiefly, but that the pneumogastric also is affected. The influence of pyridine on the pneumogastric is also shown by the increased secretion from the bronchial tubes. Pyridine therefore produces irritation of the terminal nasal fibres of the trigeminus, and hence running of the nose, salivation, and expiratory dyspnœa. The action on the bulb by means of this nerve is evident, and the respiratory centre is first stimulated and then paralyzed. This is shown by the diminution of the quantity of the air respired, and by the respiration becoming periodic and superficial. But the action of pyridine is not limited to the respiratory centre in the bulb, but also extends to the higher centre of the cortex, since it produces sleep; and this again contributes to give a periodic type to the respiration and to diminish the quantity of air respired in a given time.—*The London Medical Record*, February 15, 1887.

Pulverized Spleen in Chlorosis.—The German medical papers quote some observations made by Dr. Predazzi, at Professor Maragliano's request, on the value of treating chlorotic patients with an emulsion of pulverized spleen, bitter almonds, and brandy. In the five cases in which this was adopted, rapid improvement took place both in the general condition of the patients and in the physical signs; that is to say, the number of red blood-corpuscles was increased, as also the arterial tension and the body-weight. The author does not attempt any explanation of the action of this singular remedy. The quantity of "pulv. splenic." given daily was about five ounces, and it was ordered at meal-times.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, April 2, 1887.

THE REGISTRATION OF CONTAGIOUS DISEASES.

WE referred recently to the fact that physicians very frequently neglect to comply with the law requiring a notification to the health authorities of every case of contagious disease occurring in their practice. It is not in the matter of reporting contagious diseases only that physicians are negligent, but they are almost equally remiss in regard to certificates of birth.

We do not wish to invent excuses for this neglect of their plain duty on the part of members of our profession in this city, but it will do no harm to look a little into the causes of this neglect, to see if there may not be some remedy for it.

In the first place, forgetfulness will account for many cases of omission in this respect. The physician has no intention of evading the law, and he really means to report his cases, both of contagious diseases and of births. But somehow the days slip by, other things come along to occupy the attention, the duty of reporting the case is forgotten, and one more glittering stone is added to the mosaic of that populous region which is said to be paved with good intentions.

Another, and perhaps more frequent, cause of this neglect is a certain feeling that the law is unjust in that it demands labor on the part of the physician for which he receives no compensation. He is put to considerable labor and a slight expense for which he is not requited, but the omission of which exposes him to the penalty of a fine. And it must be said that the Board of Health does not always second the efforts of those who really wish to comply with its demands, for we have known of instances in which physicians have applied again and again for the necessary blank forms and have never received them. Very naturally they are discouraged by such treatment, and think that the matter can be of but little moment if the health authorities themselves will not aid them to so slight an extent.

This is really a more serious matter than the thoughtless are wont to suppose. In the first place, it renders the statistics of the Health Department worse than useless, for it causes them to be misleading. In the case to which we referred in a previous issue, the figures of the Board of Health made it appear that the mortality from typhoid fever in this city was over forty-one per cent., but everyone knows that this percentage is much too high. Again, the failure to report every case of contagious disease undoubtedly increases the danger of epidemics. And, finally, as regards the failure to report births, a real injury may be done to the child, as in after-years the individual may suffer great loss from being unable to produce a record of his birth.

There is, however, a simple remedy which would obviate all this. Let the authorities pay the physician for his trouble in making a report, and we venture to say that both the forgetful and the intentionally careless would vie with the thoroughly conscientious in notifying promptly the Board of Health of all cases of this nature occurring in their practice. This is done in some of the States, and is, we are informed, found to work well. The compensation need not be large, for the physician is willing to do his share if only he feels that he is not being imposed upon. And then the penalties for non-compliance with the law can be more strictly, and more justly, enforced. Such a plan would have the effect, at least, of making the statistics of the Health Department, as they should be, of real scientific value.

THE TREATMENT OF NEURALGIA BY CHLOROFORM DIFFUSION.

THE treatment of neuralgia is often so unsatisfactory that any plan that promises to remove the difficulty even in a measure is worthy of consideration. No excuse, therefore, is necessary for calling the attention of the readers of THE MEDICAL RECORD to a method recently proposed by Adamkiewicz for the relief of this troublesome affection (*La Riforma Medica*, No. 25, 1887).

The experiments of Wagner had shown that, if the positive electrode were impregnated with a solution of cocaine, the passage of a constant current produced an intense anæsthesia of the skin. This fact led the author to try what effects could be obtained by chloroform applied in the same way. He found that simply saturating the electrode was insufficient, as the substance evaporated so rapidly that frequent renewals were necessary, thus causing interruptions in the application. He therefore devised an electrode containing a receptacle for the chloroform, which was allowed to escape only very slowly, so as to keep the surface of the electrode constantly moist. This "diffusion electrode," as it is called, consists of a metallic cylinder, containing the chloroform, and closed by a diaphragm of carbon, which is a good conductor and at the same time allows the drug to leak out slowly.

The cathode is applied at an indifferent point, while the anode, the diffusion electrode, is placed over the seat of pain. The patient complains at first of a slight burning sensation, but this gradually passes away as anæsthesia becomes complete. It is important not to employ a current of too great intensity. It is best to begin with a current of moderate intensity and to increase it gradually until the limit of tolerance is reached. This limit is usually from three to seven milliampères.

This method has given very satisfactory results in neuralgia of the fifth nerve and its branches, in intercostal neuralgia, and in rheumatic pains. It would appear, also, to be a convenient means of producing local anæsthesia, as the anæsthetic area extends for a considerable distance around the point of application of the electrode.

THE POSITION TAKEN DURING SLEEP.

A VERY large number of adults form the habit of sleeping in one particular position, such as lying upon their right or left side. A smaller number sleep upon the back. Some persons sleep with the head greatly extended; more often it is flexed considerably upon the trunk. Many must have the head greatly elevated; others can only sleep with the head very low. Some observations made by Dr. G. Nosovitch (*Wratsch*) upon 235 soldiers showed that 37.5 per cent. slept upon the right side, twenty-three per cent. on the left, and 6.5 per cent. on the back.

It has yet to be determined whether any particular harm can come from sleeping in a certain position which the individual unconsciously assumes. A popular belief exists to the effect that the liver, being a heavy organ, tends to press upon the other abdominal viscera when a person lies on the left side. At any rate, more persons, probably, sleep on the right side than on the left, as experience and Nosovitch's statistics show. The author in question believes, also, that the posture in sleep influences the extension of a bronchitis. He found, for example, that in the 235 cases referred to, all of whom had this disorder, in 97 it was left-sided, in 72 right-sided, and in 66 on both sides. He thinks that the preponderance of the bronchitis on the left side was due to the fact that there was a greater expansion of this side during sleep, and, consequently, a greater ingress of cold air or of the morbific particles causing the disease.

Some writers have thought that the position in sleeping has an influence upon the passage of fæces through the colon, the position on the right side being especially unfavorable to emptying the colon. Repose on the left side, on the other hand, favors the gravitation of fæces from the transverse into the descending colon, and is therefore to be preferred by those suffering from habitual constipation (J. S. Jewell).

A recent writer has argued strongly for the view that the head should be lower than the feet during sleep, and he claims that more perfect health and greater longevity will result from such approximate topsy-turviness. The contrary position, with the head and trunk considerably raised, sometimes relievescra mps in the legs. It is well known that some chronic nervous affections, more particularly nocturnal epilepsy and some forms of insomnia, are sometimes benefited by sleeping in a partially erect posture.

It appears, therefore, that the posture during sleep is a matter deserving of some attention from physicians, and that some actual therapeutic results may be obtained by looking after its details.

A GERMAN WAY OF DEALING WITH THE QUESTION OF THE EXCESSIVE SUPPLY OF DOCTORS.

THERE has been a steady increase in the number of medical students and medical graduates at the German universities during the past few years. In the nine Prussian universities, for example, there were 3,538 medical students during the semester of 1885–86, while this year the number has increased to 3,682.

The increase in the number of physicians in Germany has evidently not been attended with corresponding benefit to the body medical as a whole. At least, this must be the conclusion drawn from the fact that at the recent annual meeting of the German Physicians' Association, a society organized in the social and economic interests of the physician himself rather than his science, an address was issued advising young men against entering the medical profession, "as the prospects of doctors are becoming worse yearly."

Although overcrowding has been one of the most patent and potent evils in the profession of this country, our own American Medical Association has never made any efforts worthy of the name to mend the matter. The plain and persistent presentation of the facts in the case by THE MEDICAL RECORD and other journals independent of collegiate interests, has accomplished something, and will, we believe, do still more. We do not, in fact, recommend the German way of formally announcing to the public that our ranks are already full enough for comfort. It smacks too much of the tradesman's attempts to limit competition. It is a fact of some importance to us, however, to learn that the prospects of the physicians in Germany are yearly becoming worse. For, doubtless, if true, this means that we shall yearly have a larger instalment of the pure-bred German physicians sent over to us. As our colleges only turn out from four thousand to six thousand new doctors every year, the prospect is, of course, most pleasant.

AFEBRILE PNEUMONIA.

OCCASIONALLY, in the aged, a croupous pneumonia, typical in every other respect, may be observed to run its entire course without any elevation of temperature. Such cases are rare, yet the possibility of their occurrence is well recognized by those who have a wide experience in the treatment of diseases in the aged, and, doubtless, they are more common than is generally supposed. The idea of a pneumonia running its course with no elevation of temperature is so contrary to ordinary experience that it may well happen that such cases often escape recognition.

It has long puzzled clinicians to account for this phenomenon, and it still awaits a perfectly satisfactory explanation. It has been shown that when uræmia is induced in animals there is a notable reduction in the body-temperature, and herein lies a possible explanation of the absence of pyrexia in these cases of senile pneumonia.

Dr. Giuseppi Lapponi relates a case, in *Il Raccoglitore Medico* of January 10, 1887, which would seem to sustain this theory. It concerned a woman, aged seventy-four, whose life had always been a hard one, and who had endured privations of many kinds, but had never suffered from any severe illness since her childhood. She was suddenly seized, while in apparently perfect health, with a chill, great oppression in breathing, and a dry and troublesome, though not very frequent, cough. The patient was greatly prostrated, had anorexia, thirst, and some dulness of the mental faculties. The temperature was 98.2 F., pulse 80, respirations 30. The physical signs pointed unmistakably to acute pneumonia in the left lower lobe posteriorly. Thermometric observations were repeatedly made throughout the course of the dis-

ease, but the temperature was never found to rise above the normal height. Examination of the urine gave evidences of a chronic nephritis. The tongue was very dry, there was complete anorexia, and the pupils were irregularly dilated, signs which the writer took to be indicative of a slight degree of uræmic poisoning, and it was to this cause that he attributed the entire absence of fever.

There may, of course, be, and doubtless are, other conditions which, occurring coincidently with pneumonia, would tend to prevent a rise of temperature such as normally takes place, but this observation would seem to show that one cause, at least, of apyrexia in acute diseases in the aged may be chronic nephritis giving rise to a mild degree of uræmia.

SPLENIC TISSUE AS A THERAPEUTIC AGENT.

Some curious experiments have recently been made by Dr. Predazzi with the pulp of the spleen, with a view of determining its value, if it has any, in the treatment of anæmia. A mixture was made containing brandy, one and one-half ounce; splenic pulp, four and one-half ounces, and emulsion of bitter almonds, ten and one-half ounces; the whole to be taken in the course of the day with the meals. Five patients with chlorosis were treated with this mixture, and in the course of from one to three weeks the following results were observed by the author (*Deutsche Medicinal-Zeitung*):

1. Rapid improvement in the general health, and increase in the number of the red blood-globules.

2. A speedy and permanent cure of the functional disturbances of the nervous system, digestive and urinary organs, and circulatory apparatus.

3. Increase of arterial tension and of the body weight.

The patients were, however, put at the same time upon a nourishing and regulated diet, and it is, therefore, somewhat difficult to say how much of the benefit was derived from the spleen pulp, and how much from the good food, to which the patients were doubtless not accustomed. We venture to suggest, however, that the latter was at least equally as potent for good as the chopped-up spleen.

MEDICAL LEGISLATION IN WISCONSIN.

The *Evening Wisconsin*, a Milwaukee paper, strenuously opposes the present bill to regulate the practice of medicine in its State. It says in effect that the proposed bill is revolutionary, and that Wisconsin is all right as it is, its death-rate being low and its doctors highly intelligent. The bill, which we have examined, is not so alarmingly radical as the *Wisconsin* seems to think, and that paper has certainly some misconceptions about it. A mixed Board of Examiners is provided for, who certify the diplomas of those having such documents, and who examine persons who do not have them. The Board is appointed by the Governor from nominees of the three State societies. This is objected to, because Wisconsin has 2,000 physicians, of whom only 400 are members of the State medical societies. All, however, can and should have such membership. The bill is, in general, much like other bills that have worked successfully in other States.

Perhaps the columns of profitable quack advertisements which we see in the *Evening Wisconsin* may bias our esteemed contemporary somewhat against the "too severe" regulation of medical practice. We observe that it announces the merits of two Milwaukee quacks who prey upon the sexual troubles of young men. Such gentlemen pay from $100 to $1,000 a month for advertising.

At any rate, while the bill the *Wisconsin* attacks may have some objectionable features, the general principle that a community should supply its citizens only with educated physicians is a good one and one that is constantly gaining ground.

SOME NEW REMEDIES.

The following are a few of the more recently introduced therapeutical remedies which have been recommended as of more or less efficacy in the treatment of a number of diseased conditions. Whether or not they will prove, on more extended trial, to be as valuable as their sponsors believe them to be, time and experience alone can show.

The carbolate or phenate of mercury has been recommended very highly by Dr. P. Gamberini in the treatment of syphilis. It is given in the form of pills, each containing one-third of a grain. At the commencement two pills are given a day, and the number is gradually increased to six. If given in larger dose, the salt is liable to cause some gastro-intestinal irritation and, occasionally, ptyalism. The author reports ten cases of syphilis treated with phenate of mercury, and states that he has records of many more in which similar results were obtained (*La Riforma Medica*). The time from the first exhibition of the salt until the disappearance of all syphilitic symptoms was, in six cases, from twelve to twenty days; in three, from twenty-five to forty-five; and in one case, seventy days. In doses of from two-thirds of a grain to one and a third grain in the twenty-four hours the drug was well borne by all, but when the dose was raised to two grains a few patients showed slight symptoms of intolerance. In one case even small doses caused intestinal colic, and in three cases a moderate degree of ptyalism was produced.

Tulipine is an alkaloid which has been extracted by Gérard from the common garden-tulip, *Tulipa gesneriana* (Linn). Its chemical and physiological properties have been compared to those of colchicine, veratrine, and scillitine (*Les Nouveaux Remèdes*). It unites with acids to form salts. A dose of one grain and a half is sufficient to cause death when administered to cats, the fatal result being due to paralysis of the heart. In medicinal doses of one-twelfth to one-tenth of a grain it increases the salivary secretion, is diuretic and laxative. Besides its effects upon the heart and intestinal tract, it acts also upon the central nervous system. All parts of the plant furnish the alkaloid in considerable proportions.

Methylol is an ether in which two atoms of hydrogen have been replaced by two of oxide of methyl (*Los Medicamentos Modernos*). It is a colorless fluid, soluble in water, alcohol, and the fixed and volatile oils, having an odor resembling chloroform and acetic ether, and an aromatic taste. When internally administered it is said to induce profound sleep, which is, however, not

of long duration, owing to the rapid elimination of the drug. It excites no irritation of the stomach, but, on the contrary, relieves nervous pains of this organ and of the intestines. Applied externally, in the form of an ointment or of a liniment, it is lauded as an excellent local anæsthetic analgesic. Its therapeutical indications would seem to be many, as it is said to be a perfect substitute for chloral in all cases in which the stomach is irritable and in which, for that reason, chloral is not well tolerated. On account of its prompt action and rapid elimination, methylol is of value as an hypnotic in the delirium accompanying acute febrile affections. The applications of the drug as an analgesic are very numerous, since it is indicated in all cases in which it is desired to diminish pain and reduce local hyperæsthesia. It may be given in doses of four minims every ten minutes, until the desired result has been obtained, or until four doses have been taken.

Catramine is another remedy which Dr. L. Casati, writing in the *Raccoglitore Medico* of March 10, 1887, characterizes as of great value. It is an oil obtained by Bertelli, by means of distillation, from the gum (*catrame*) of the *Pinus canadensis*. It is of a straw color, having a faint and rather pleasant odor of turpentine, is soluble in ether and alcohol, and slightly so in water. It has an agreeable balsamic taste, and is taken readily even by children. It is said to increase the appetite and to promote digestion. It is recommended very highly in the treatment of affections of the respiratory apparatus, catarrh, chronic pneumonia, incipient phthisis, etc. In other catarrhal conditions, as of the stomach, intestines, and especially of the bladder, its good effects are said by Casati to be most marked. In all affections, indeed, of the genito-urinary apparatus it is vaunted as being superior to copaiba or any of the commonly employed balsams. It is prepared by a special process, and would seem to be a proprietary article, and so, we fear, like many other preparations, it will never come into general use as a legitimate therapeutic agent, even though it may be as excellent a remedy as Dr. Casati and others seem, from their present experience, to think it to be.

THE INFLUENCE OF THE EMOTIONS IN THE ETIOLOGY OF SKIN DISEASES.

It has long been a question whether a cutaneous eruption may be caused by a purely mental process apart from any other apparent etiological factor, and not a little controversy has arisen from it. It is now, however, pretty generally conceded that such a cause is competent to produce, not only cutaneous lesions, but also morbid processes in other organs and parts of the body, and numerous cases of this nature are on record.

Dr. Tommasoli, in a recent memoir (*Revista Médica de Sevilla*), upholds the opinion that various cutaneous eruptions may follow upon, and be caused by, violent emotions, and cites several cases in support of this view. The first case was that of a young woman who was suddenly attacked with a pemphigoid eruption immediately after receiving the news of the death of her husband. In another instance a lady presented an eczema, covering the eyelids, neck, arms, and vulva, which made its appearance very suddenly after it had been announced to her that her daughter had committed suicide. A third case was that of a man who had been threatened with personal injury by a debtor whom he had importuned for payment. He was greatly frightened, and was almost instantly seized with an acute dermatitis accompanied with a pustular eruption covering the back and extremities.

These cases by themselves would hardly suffice to establish the truth of this causal relation between emotions and skin eruptions, but they are valuable in the way of cumulative evidence, taken in connection with the numerous other reported instances which tend to confirm this theory.

News of the Week.

Another State Board of Health.—Nebraska has established a State Board of Health. The new law provides that the Governor shall appoint seven persons, two from each Congressional District, and one at large, with the Governor as their presiding officer. Persons appointed must be graduated physicians, of at least ten years' consecutive practice, and the term of office is to be seven years.

Malignant Measles in Kansas City.—Dr. John Fee, City Physician of Kansas City, has given notice to all physicians to report cases of measles. He reports more deaths from measles than from diphtheria and scarlet fever combined, and proposes to placard houses containing cases of the disease.—*Sanitary News.*

The Death of Professor Horner, of Zurich, well known as an ophthalmologist, is announced.

A Curious Way to Advertise.—The local paper of a town in West Virginia announces that a Dr. C. B. Blubaugh, of Huntington, "has been highly honored by the Royal Society of England for important surgical operations." This sounds imposing, but it is nonsense all through, since the Royal Society in question has nothing to do with surgery, or medicine either, except as a part of general science.

We are glad to find that classical learning is not confined to Boston or Chicago. Dr. H. Plageman, of Hustisford, Wis., a town which should be better known than it is, sends us his translation of the Greek sentence written on the Boston doctor's slate (*vide* Medical Record of March 5th). It is: "My relatives want me to come home." Hustisford should be represented in the International Congress.

A Western View of it.—The *Weekly Medical Review*, of St. Louis, says: "The consulting physicians in the case [of the late Mr. Beecher] with Dr. Searle were Dr. W. Todd Helmuth, of New York (formerly of St. Louis), a homœopath, and Dr. William E. Hammond, of the College of Physicians and Surgeons of New York. Little incidents like these 'show up' the 'true inwardness' of the 'new code' or 'no code' men in New York." The only mistakes here are that Dr. William A. Hammond was the man, not William E.; that he is not of the College of Physicians and Surgeons; and that he did not meet Dr. Helmuth in consultation at all. Little paragraphs like the above should be written with more care.

The North Carolina State Medical Society will hold its next annual meeting at Charlotte, on April 13th, 14th, and 15th.

A great many Revolutionary Things have been accomplished on paper and by resolution. Nothing has been proposed, however, much more radical than that of the Ohio Sanitary Association, which recently "*Resolved*, That it is the sense of the Ohio State Sanitary Association that syphilis should be made a legal bar to matrimony." Adopted unanimously.

How Dr. Oliver Wendell Holmes relieved his Asthma.—In the first instalment of Dr. Holmes' entertaining article in the *Atlantic Monthly* for March, giving an account of his trip to Europe, the experiences of the writer in overcoming his attacks of asthma are related. All kinds of prescriptions were showered upon him, but Dr. Holmes announces that nothing did him so much good as a certain patent asthma-cure, made in Providence, R. I. The composition of this is said to be:

℞. Pulv. lobelia,
Pulv. stramoniæ fol.,
Pulv. potas. nitrat.,
Pulv. black tea..... .....āā ʒ ij.
M. and sift.

Some of this is burned and the smoke inhaled.

The Society of the Alumni of Bellevue Hospital is the name of a new medical society organized in this city. As there is no institution, so far as we know, of the above name granting diplomas, we are at a loss to understand what the society in question is composed of. Bellevue Hospital is a public hospital belonging to New York City, and cannot possibly have any alumni in the ordinary sense of the word. Bellevue Hospital Medical College is a teaching institution, entirely separate, officially, from the hospital. We advise the young society to rechristen itself. Having secured nomenclatural lucidity, we will then wish it all possible success.

Cocaine now costs about a cent and a half a grain.

Geographical Representation and the American Medical Association.—The *Medical News* states that, upon examining the list of officers of Sections of the American Medical Association for the next annual meeting, it will be observed that of sixteen positions Illinois has four, Missouri three, Maryland two, and New York, Pennsylvania, New Jersey, Ohio, Kentucky, Arkansas, and Minnesota, each one. Two States—Illinois and Missouri—furnish nearly one-half of the appointees. The records of the meetings show that for three consecutive years they have or will have been held considerably west of the centre of our country's population. Even admitting the superiority of Western medicine, the above distribution of officers seems hardly democratic, or in harmony with the eagle-screams heard when the appointments of the International Congress were first announced.

Conditions of Successful Production of Local Anæsthesia in Tooth-Extraction.—Dr. A. Lebrun, of Brussels, and his house-surgeon, M. Andries, have published the notes of twenty-nine cases in which they employed local cocaine-anæsthesia for the extraction of teeth. In twenty-three cases the anæthesia was complete, in one case partial. In the remaining five cases the procedure was unsuccessful. This is attributed by them to the difficulty of introducing the short, straight needle of the ordinary hypodermic syringe in the case of the second and third molars, and also, perhaps, to no precautions having been taken to prevent the escape of the liquid. They point out that M. Viau, of Paris, who succeeded in producing complete anæsthesia in every one of his eighty-six cases, made use of a specially constructed syringe, with a holder by which it could be grasped firmly between the index and middle fingers, and provided with needles of various degrees of curvature; also, that he surrounded the tooth with plugs of cotton-wool, and applied the finger over the puncture after the withdrawal of the needle. Besides which he made the patient keep rinsing his mouth with cold water during the five minutes that intervened between the introduction of the cocaine and the actual operation. These precautions were not observed by MM. Lebrun and Andries. They used, however, a solution similar to that of M. Viau—viz., fifty centigrammes (seven and a half minims) of a two per cent. solution of carbolic acid containing five centigrammes (three-fourths of a grain) of hydrochlorate of cocaine, half of which quantity was injected into each surface of the gum.—*Lancet.*

Studies for Medical Students.—The Berlin Medical Faculty recommend for medical students the study of meteorology, mineralogy, geology, anthropology, psychology, and logic. This is a very poor selection, for American medical students at least. Anthropology, psychology, and logic are well enough; but for the rest, *belles lettres* and the humanities are better far than the 'ologies, since they teach human nature and the art of expression, things much needed in the very human work of dealing with the sick.

The Tenement-House Law recently enacted by the New York Legislature is a measure which will doubtless promote better health and more comfortable living among the laboring classes of our city. The measure was advocated and carried through largely by the *Morning Journal*, and that paper deserves credit for its success in practical philanthropy.

A Duel talked of.—We learn with pain that a personal altercation has occurred between Dr. Love and Dr. Todd, of St. Louis. Dr. Love, having editorially criticised Dr. Todd some time ago, was snubbed by the latter, who in turn was immediately struck by the former. These interchanges of opinion were then suspended temporarily, but a resumption of hostilities is talked of. Dr. Love is President of the Mississippi Valley Medical Association, and highly esteemed as a physician, besides being a stalwart advocate of the American Code of Ethics.

The Myxœdema Committee of the Clinical Society of London has completed its investigation of the etiology, symptoms, and morbid anatomy of this interesting disease, and it is now engaged in studying the question raised by Professor Kocher's observations of the effects of total extirpation of the thyroid gland. For this purpose Dr. Felix Semon has issued a letter to all surgeons who are known to have performed this operation, asking for a statement of the results observed.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN SURGERY.

Stated Meeting, March 14, 1887.

ROBERT F. WEIR, M.D., CHAIRMAN.

DR. C. H. WILKIN presented several patients who illustrated the results of (see p. 378)

SUTURED TENDONS.

THE CHAIRMAN said that he had practised suturing of tendons in several cases and with good results.

DR. BOLDT asked if, when the operation was performed some time after the receipt of the injury, it was necessary to freshen the ends before uniting them.

THE CHAIRMAN said that it had been found necessary to dissect upward farther, in order to secure the upper end of the tendon, than it had been when the operation was performed at an early date. In either operation, the primary or the secondary, the extent of the cut upward, in search of the upper end, could be lessened by making traction with a bandage from above downward.

DR. MOORE presented a patient with

A GLOBULAR PULSATING TUMOR IN THE REGION OF THE HEART.

There was no bruit. The heart was only slightly displaced. There was a distinct history of syphilis dating back six years. About one year ago she noticed that her left arm was enlarging and was bluish. Some time afterward she noticed that there was some trouble in the region of the heart, and about four months ago the tumor in the region of the heart was first seen. It was supposed that it was an aneurism of some portion of the aorta.

DR. JOHN A. WYETH then read a paper entitled

LAPAROTOMY AND INTESTINAL SUTURE—EXSECTION OF A PORTION OF THE ILEUM WITH RESTORATION OF FUNCTION OF THE ALIMENTARY CANAL.

Leah R——, Russian, fifty-six years of age, housewife, was admitted to Mount Sinai Hospital October 9, 1886, with a swelling as large as an ordinary fist occupying the inner aspect of the left groin and thigh.

The skin over the tumor was red, tender, and doughy, and fluctuation was evident. The surrounding tissues were slightly emphysematous. She had been in her present condition ten days in a tenement house. Her temperature was normal.

Diagnosis: Strangulated femoral hernia. Ether was administered, and the tumor was incised, when several ounces of foul pus mixed with intestinal matter were discharged; the mass was gangrenous, and an opening into the intestine was detected. This opening was dilated with a pair of dressing forceps to secure a free exit of intestinal contents, and a loose dressing of iodoform gauze was laid over the wound. Only a small quantity of matter escaped when the gauze was changed every second or third day.

Thirteen days after the first operation ether was administered, laparotomy performed, two inches and a half of the intestine with a triangular piece of the mesentery removed, and the edges of the wounds united by sutures. The edges of the divided mesentery were united first, and by eight interrupted catgut sutures, about one fourth of an inch distant from each other.

The mesenteric attachments of the ends of the cut intestine were brought carefully into apposition and secured by three kinds of sutures: (1) A suture through the mucous membrane alone, or Czerny's suture; (2) a suture through the peritoneal coat alone, or Lembert's suture; (3) a suture which pierced the peritoneal coat, and, passing along with the muscular layer, came out upon the free border of the divided gut, the intermediate suture.

In suturing the intestine, the very finest black (iron-dyed) silk and a delicate, perfectly straight round needle were used. The silk was made aseptic in sublimate solution (one to three thousand), and it and the needle taken from a one to twenty carbolic acid solution as they were used.

The cavity of the gangrenous abscess was scraped out with a Volkmann's spoon and rendered thoroughly antiseptic, the opening into the intestine plugged, and the whole cavity packed with iodoform gauze before the laparotomy was commenced. Also when the loop of intestine, five inches above and below the occlusion, had been drawn out of the abdomen, a piece of cotton tape one-fourth of an inch wide was tied four inches above and below the limits of the gangrenous opening, so as to completely occlude the lumen of the gut.

The operated lasted four hours. Recovery took place without unfavorable spmptoms. There is no sign of obstruction or interference with the functions of the alimentary canal, and the hernia, at this date, is radically cured.

With reference to the treatment of

STRANGULATED HERNIA WITH GANGRENE OF THE INTESTINE,

Dr. Wyeth said that establishing a permanent fecal fistula at the seat of the gangrene should be consigned to subjects so feeble that no operative procedure was justifiable.

Whether or not the gangrenous portion should be immediately exsected, the ends of the gut reunited by suture, and the loop returned to the abdominal cavity, must be determined by the condition of the patient at the time of the operation. In most cases, however, the condition of the patient is not favorable for immediate exsection. In such cases the plan carried out in the case just described should be followed.

The difficulties of the operation, however, are great, and the time required dangerously long, unless the surgeon has had sufficient practice to enable him to work rapidly and safely.

DR. ROBERT ABBE thought there was a possibility that the brilliant result obtained by Dr. Wyeth might lead some to adopt the method of treatment described in cases in which recovery would take place spontaneously; for fecal fistula following gangrene in femoral hernia was quite frequently healed by nature. Again, the use of Dupuytren's enterotome was much less dangerous than laparotomy. Besides, a laparotomy that required four hours for its performance endangered the life of the patient very much on account of the liability to the occurrence of acute nephritis after prolonged etherization. On this account he thought that, in such cases, an operation should be delayed for a longer period than three weeks, say, to two or three months, before attempting to close the intestinal fistula. He then related a case which he treated with Dupuytren's enterotome.

THE CHAIRMAN had not yet met with a case of gangrenous femoral hernia with fistula following but what had healed eventually without operation, and therefore he recognized the justice of Dr. Abbe's criticism, while at the same time he appreciated the advantage mentioned by Dr. Wyeth of not performing resection at once; for, the inflamed condition of the intestine, extending beyond the parts immediately involved, rendered the union much more insecure than that obtained by operating some time afterward. Besides, the general condition of the patient forbade, as a rule, a prolonged operation.

TO MAKE AN ARTIFICAL ANUS WAS MUCH SAFER,

and subsequently it could be determined what surgical procedure, if any, was best adapted to the case. The mortality of resection done for artificial anus was much less than when it was performed for hernia, it being only thirty-eight per cent. The fact of the surgeon's inability to feel certain that he could unite the intestine so that it would be free from leakage was one that was entitled to the highest consideration.

Dr. Robert T. Morris suggested a flap operation that would allow both sides of the intestine to be supplied with blood from the mesentery, and, at the same time, prevent the peristaltic action from making traction upon one point, and this, also, he thought would diminish the liability to the occurrence of stricture. He asked Dr. Wyeth if he thought that he would require four hours to perform the operation in another case.

Dr. Wyeth said that it was very difficult to say what length of time would be consumed by any operation; but, under circumstances throughout identical with those under which the operation in this case was performed, it was quite probable that the time would be considerably shortened. He thought that the dangers arising from peristalsis need not be very much considered. One objection to the flap operation would be an unnecessary prolongation of the operation, as it would certainly be more difficult to unite the edges than those of a simple straight cut.

As to the suggestion that the case might have yielded to Dupuytren's enterotome, Dr. Wyeth had not had one in which he had tried it, although he regarded it as a good and conservative operation. But he doubted whether the results in the cases in which Dupuytren's operation had been performed would encourage its repetition, if there was another which was comparatively safe. The question of leakage certainly was an important one, but its importance, he believed, would be reduced by the more careful surgery of the future.

The section then adjourned.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE COLD-BATH TREATMENT OF HYPERPYREXIA—EPILEPSY AFTER GUNSHOT WOUNDS CURED BY STRETCHING THE SCIATIC NERVE—HÆMATURIA IN CASES OF GRANULAR KIDNEY—CÆSAREAN SECTION FOR UTERINE FIBROMYOMA—THE STATUS OF ARMY MEDICAL OFFICERS—UNIFORM VS. PRIVATE CLOTHES.

London, March 5, 1887.

At the last meeting of the Clinical Society, Dr. Carrington, Assistant Physician to Guy's Hospital, brought forward a case in which he had successfully employed the cold bath in treating the hyperpyrexia of acute rheumatism. As Dr. Carrington very truly remarked, there is still among patients and their friends (and also, I might add, among practitioners) considerable prejudice against this remeny, even in desperate cases. Dr. Carrington's patient was a medical student, aged twenty-three, who had so far recovered from a mild attack of acute rheumatism (under salicylic acid treatment) that he had left his bed. On taking his temperature one day at noon it was found to be 107°, but soon afterward fell to 106°. Dr. Carrington then saw him and thought it desirable that he should be removed to a private ward in Guy's Hospital. During the journey thither he became delirious, and on arriving at the hospital was livid and unconscious with a temperature of 109.8°. He was at once placed in a bath of water at a temperature of 70° F. By adding pieces of ice, the water was cooled down as rapidly as possible, but the heat of the body was so great that, although considerable quantities of ice were used, great difficulty was experienced in cooling the water. Pouring ice-cold water on the head, however, produced some effect. Fifteen grains of antipyrin were also administered per rectum. The patient was kept in the bath for an hour, by which time the rectal temperature had fallen to 102.4°. He was then taken out and covered with a sheet. Tetanic convulsions then came on, but gradually ceased, and by 7 P.M. his temperature had fallen to 97.2°. In another hour consciousness returned, and he was able to take nourishment (milk). During the next day he remained comfortable, and salicylate of soda was given. By midnight, however, his temperature had risen to 103.8°. Fifteen grains of antipyrin were given, but failed to reduce the temperature, and as by 2 A.M. this had reached 105.2°, the ice-bath was given again for fifteen minutes. As the temperature had then fallen to 101°, he was removed, but again replaced in the bath at 6 A.M., as the thermometer indicated a temperature of 105.4°. A quarter of an hour's immersion again acted efficaciously, and sleep followed. At 2 P.M. a third bath (of forty minutes' duration) was given, as the temperature had again reached 105°. After this no further hyperpyrexia occurred. The temperature was, indeed, normal, except on one occasion when, with a return of pain, it reached 101°. Salicine was substituted for the salicylate of soda, and the patient made a good recovery.

A short discussion ensued on the reading of Dr. Carrington's paper. Dr. Hale White commented on the failure of both antipyrin and the salicylate of soda to reduce the temperature, and suggested that we might, in time, discover that each drug was applicable to a particular class of cases. The President (Dr. Broadbent) said he had never seen convulsions occur during the rise of temperature. He had seen them come on during the cold bath in a case which ultimately terminated fatally, and had seen hyperpyrexia supervene during the use of salicylate of sodium. Dr. Stephen Mackenzie said he had had several cases of hyperpyrexia in private practice. All had terminated fatally. Convulsions, when present, were tonic.

Dr. Hadden brought forward the case of a man in whom epileptic fits had followed a gunshot-wound of the calf. The fits first came on four months after the injury, by which time the original wound had quite healed. The sciatic nerve was exposed and stretched. After this the attacks ceased, but the patient suffered from severe paroxysmal pain in the calf, followed by the same sensations as if a fit were coming on. Dr. Hadden referred to the experiments of Brown-Séquard and Horsley, who had induced epilepsy in guinea-pigs by injuring the sciatic nerve. Mr. Anthony Bowlby related a case in which epileptic fits followed a gunshot-wound of the leg, but were cured by stretching the sciatic nerve. Mr. Bowlby then read a paper containing the particulars of three cases of granular kidney in which hæmaturia occurred. He observed that these cases were of importanee in connection with diagnosis. In one of the cases the hemorrhage was so free that it was thought to proceed from the bladder. In others, the diagnosis had to be made from other of the more recognized causes of renal hemorrhage, especially calculus. Dr. Carrington remarked on the rarity of these cases. Dr. Maguire thought hemorrhage, in cases of granular kidney, was not so rare as stated. Patients sometimes seemed better after slight hemorrhages. Dr. Broadbent said severe hemorrhages were undoubtedly rare. He had, however, seen one case where the patient bled to death in spite of treatment.

At this week's meeting of the Obstetrical Society, Dr. Horrocks, Assistant Obstetric Physician to Guy's Hospital, described a case of obstructed labor and exhibited the uterus removed after death, with the fibro-myoma which had prevented delivery *per vias naturales*. Labor had come on at term, and the waters had come away. Pains continued for five weeks, but without effecting delivery. Meanwhile disintegration of the fœtal skull had occurred and portions came away. The patient being seen in this stage, Cæsarean section was performed, but the patient died almost immediately. The fœtus removed was putrid.

The recent Army Warrant abolishing "relative rank" among army medical officers has caused some consternation, not unmixed with bewilderment, in military medical circles. Questions have been asked on the matter in the House of Commons, and a few days since the Sec-

retary of State for War replied that "the abolition of the term 'relative rank' has not altered the position of medical officers in any respect whatever." This has reassured some. On the other hand, many of those concerned argue that even if it be only a paper dignity, the taking of it away must make some difference. For years the tendency has been to treat the medical officers worse than those of any other non-combatant department. They, therefore, naturally wish to retain what little position they have. One gentleman has sarcastically written to the journals to suggest that, as in future medical officers are to have no recognized status in the army, they might as well be relieved from the expense and encumbrance of wearing uniform. The latter, indeed, is by no means a source of pride to those who don it, and medical officers of high rank take the advantage of their position to appear as much as possible in civil dress. In this they but imitate the combatant officers, who, as soon as they are off duty, hasten to resume the garb of civil life. The wearing of uniform, indeed, is felt by them to be not a privilege but a burden, only to be endured when on duty, on certain public occasions, and perchance at a ball. When the officers act thus it is no wonder that the men should feel similarly. They are, indeed, obliged to wear uniform always, but can obtain *special permission* to wear private clothes when on their annual furlough. This contempt of military uniform is, to some extent, shared by the public, and a private soldier inspires much less awe than a policeman. It is different abroad, and when Lord Wolseley accompanied the Prince of Wales through Germany wearing private clothes, those who saw him in public could with difficulty believe him to be our celebrated general. It has been more than once mooted that doctors should, like clergyman, dress in a particular way, so that they may be recognized everywhere. The proposal, however, has not been favorably received. Clerical garb, though, commands respect everywhere, and even the hideous wigs worn in court by legal luminaries fail to excite derision. Why, then, should we not revert to the gold-headed cane?

OUR PARIS LETTER.

(From our Special Correspondent.)

THE SUPPOSED ANTAGONISM OF OPIUM AND BELLADONNA—THE SIGNIFICANCE OF THE HERPETIC ERUPTION IN TYPHOID FEVER—DRINKING-WATER AND DISEASE-GERMS.

PARIS, March 18, 1887.

THE notion that opium and belladonna are physiologically and therapeutically antagonistic is still entertained by many in the profession. The following note, however, recently communicated to the Paris Academy of Medicine by Professor Villemin, of Val-de-Grâce, would seem to invalidate this theory. A young artilleryman, of a strong constitution, had been affected one or two months when he was admitted to the hospital with acute diabetes with all its symptomatology, with a polyuria of fourteen and a half litres in the twenty-four hours, and a glycosuria of five hundred and forty-one grammes per day. The patient was immediately submitted to the usual classical treatment of diabetic patients (gluten bread, meat, abstinence from sugar and from farinaceous substances, alkalis, etc.), but at the end of the week there being no improvement whatever, and as the state of the patient was extremely grave, and having remembered that he had formerly cured a patient affected with diabetes insipidus with opium and belladonna combined, Dr. Villeman resolved to try this medication in the present case. He commenced by administering ten centigrammes of the extract of belladonna, and five centigrammes of the extract of opium per day. In seven days the quantity of urine descended to ten litres, and the sugar was reduced to four hundred grammes. The dose of the extracts was progressively increased, till at the end of two months the patient took fifteen centigrammes of each extract per day, and the doctor had the satisfaction of seeing that the quantity of urine and the proportion of sugar had diminished gradually. At that time the urine was three to four litres and the sugar two to five grammes per litre, and the dose of the opium and belladonna was raised to twenty centigrammes, and at the end of eight days there was no more any trace of sugar. During seventeen days the medication was continued without any reappearance of glucose. The medication was then suddenly stopped, and in the space of two or three days the sugar returned to sixteen grammes. At the end of three days more the use of the narcotics was resumed in doses of twenty centigrammes each. Five days later the sugar had again disappeared, and the quantity of urine passed was two litres per day. The cure was maintained during the time that the patient took the medicine, but as soon as it was stopped, or the doses of the opium and belladonna were diminished, the sugar reappeared and the urine augmented. During the whole period of experimentation the patient was restricted to the diet of diabetics, but after that he was allowed the diet of the other ordinary patients. This change did not produce any modification. The glucose continued to be absent so long as the opium and belladonna were maintained in doses of twenty centigrammes. By way of experiment, the bromide of potassium was administered for fifteen days, during which time the narcotics were suppressed; the sugar reappeared and mounted up to forty-five grammes, and the urine to eleven and a half litres. On the other hand, the doctor wished to know whether, of these two extracts, one of them had a preponderating or exclusive action in the modification of the malady, and he established that the results obtained were due to their association. The patient referred to above, after having been submitted for a month to the treatment described, left the hospital cured.

In an article in the *Revue Médicale de l'Est*,[1] Dr. Spillmann draws attention to the fact that it was for a long time maintained that herpes labialis of fevers never occurred in typhoid fever. Some authors have gone so far as to say that even when all the symptoms characteristic of typhoid fever exist, the diagnosis of typhoid fever must be abandoned, if the eruption referred to should spontaneously develop itself. Professor Hagen, of Leipzig, indicated febrile herpes among the negative pathognomonic symptoms; its presence, he stated, should always exclude the idea of abdominal typhus. Professor Hardy, of the Faculty of Paris, considered also the presence of herpes at the commencement of a febrile malady as being sufficient to remove all idea of typhoid fever. Hebra, on the contrary, maintained with other physicians of Vienna, that herpes may sometimes supervene in typhoid fever. This opinion has been confirmed by Spillmann, who in the space of a month observed the herpetic eruption in three cases among twenty patients affected with typhoid fever, and he had reason to believe that it was not a simple coincidence. Dr. Spillmann therefore concludes that febrile herpes may supervene at the commencement or in the course of typhoid fever, and that one should not consider, *à priori*, as not typhoid fever any febrile malady at the onset of which there appear vesicles of febrile herpes.

The French are beginning to be alive to the importance of attending to the purity of their drinking-water, as it has been proved that water is frequently the vehicle of the production and propagation of the germs of infectious maladies, principally of cholera, dysentery, and typhoid fever. In confirmation of this theory, Dr. Brouardel, in his report to the Paris Academy of Medicine on an epidemic of typhoid fever which occurred a short time ago at Pierrefonds, a few miles from Paris, says the cause of

[1] On the Diagnostic Value of Herpes in Typhoid Fever.

it was traced to the potable water of wells in the vicinity of cesspools, the contents of which were permanently mixed up with that water. In three houses contiguous to each other there lived twenty-three Parisians who went thither for the summer. Of this number twenty were affected with typhoid fever. Four belonging to one family (three young girls of fifteen, twenty, and twenty-three years of age, with their servant of twenty) succumbed to the disease. Of three persons of a family who were affected but escaped the disease, one had passed but twenty-four hours at Pierrefonds, the other two, having remarked a peculiar taste in the drinking-water, which they partook of only one day, resorted to the use of mineral waters instead.

As anticipated in my last, Professor Brouardel has been appointed Dean of the Faculty of Medicine of Paris in the room of Professor Béclard, recently deceased.

THE TREATMENT OF COLD ABSCESSES BY IODOFORM INJECTIONS.

To the Editor of The Medical Record.

Sir: Referring to your editorial on "The Cure of Cold Abscesses by Iodoform Injections" in The Record of March 12th, allow me to make, through the columns of your valued journal, the following statements concerning the method as practised at Professor Billroth's clinic.

Billroth uses a ten per cent. emulsion or mixture of iodoform in glycerine, and of this he injects forty to fifty grammes, equal to four or five grammes of iodoform, for each injection.

The abscess is tapped with a medium-sized trocar, the pus allowed to escape, but not washed out, the iodoform mixture injected through the same cannula, and a strip of adhesive plaster applied over the point of puncture.

Contrary to what is said to be the case when solutions of iodoform in ether are used, these injections cause absolutely no pain, except what is produced by the puncture, and the danger of distention through volatilization of ether, mentioned in your editorial, is excluded.

The injections should not be repeated as long as iodoform is excreted with the urine, which will sometimes be a number of weeks, or even months. I observed a patient at Billroth's clinic whose urine contained iodoform from an injection made over two months previously. The swelling was steadily diminishing. Months must often be allowed to show the full beneficial effects of an injection. Sometimes two or more injections are necessary to produce the desired result, but in general the final effects have been very satisfactory at Billroth's clinic.

The advantages of this method often become especially apparent in cases where the cold abscess is seated at some distance from the original disease, or where the real seat of disease cannot be attacked, *e.g.*, in abscesses from Pott's disease pointing in the inguinal or gluteal regions, or thigh, and causing large, purulent cavities in these localities, while in just such cases the treatment by incision is often not too satisfactory.

As the results obtained by this iodoform and glycerine mixture appear to be quite satisfactory, there would seem to be no necessity for subjecting patients to the pain produced by the injections of the solutions in ether; and the one great objection to the use of iodoform injections mentioned in your editorial, viz., their great painfulness, can no longer be urged against their general adoption.

I do not find the method mentioned in the last (1885) edition of "Billroth's General Surgery." My statements are according to personal observations.

H. Reineking, M.D.

Franklin, Wis., March 14, 1887.

Instantaneous Remedy for Lumbago.—Collodion, tincture of iodine, liquid ammonia, equal parts. To be applied widely over the parts with a camel's-hair brush. This applies to accidental or *a frigore* lumbago or to rheumatic pain produced by a strain or muscular exertion.

Army and Navy News.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau. Health Department, for the week ending March 26, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	10	4
Scarlet fever	54	8
Cerebro-spinal meningitis	6	6
Measles	134	15
Diphtheria	75	36
Small-pox	4	3
Yellow fever	0	0

The Causes of Wars.—A well-known French statistician has analyzed these, and arrives at the following conclusions anent them: He limits his inquiries to the last four centuries, and examines 286 wars in all. Of these, 55 were civil wars; 44 were wars of conquest and land robbery; 41 were wars of succession, or of crown claims; 30 were, as M. Leroy-Beaulieu puts it, "wars under pretence of helping allies; 28 were professedly religious wars, but most of these were waged on an old monarchical principle, *Cujus regio, illius religio;* 24 were wars of retaliation; 22 were wars for taxes; 22 were wars of commercial rivalry; 8 were wars on so-called points of honor or prerogative. Among the wickedly capricious causes of the wars of the French monarchs of the seventeenth and eighteenth centuries we find such entries as "A war for a window," and "A war for a glove."

Perils of Rural Practice.—A French rural practitioner, Dr. Pierre Seguin, driving home one evening lately, was thrown out of the carriage and killed instantaneously by the shying of his horse. In the address of condolence drawn up by the Association of Medical Practitioners in the Gironde, attention is called to the dangers to which country doctors are exposed, just as sailors who have to brave the perils of the ocean.

The Position of and Indications for Total and Partial Laryngectomy were very well presented in some remarks made recently by Mr. Lennox Brown (*British Medical Journal*): When, eight years ago, the late Dr. Foulis, of Glasgow, showed at the Medical Society the patient from whom he had successfully extirpated the whole larynx four months previously, for "papilloma and spindle-celled sarcoma," I ventured to express a doubt whether that operation would ever yield beneficial results commensurable with the immediate danger of its performance, the very short extension of life, and the discomfort of an artificial larynx to those

who survived long enough to wear one; and I drew attention to the superiority of the statistics of tracheotomy to those of the radical operation. Dr. Foulis' was the eighteenth complete extirpation, and the second which survived more than nine months, for his patient lived a year and a half, and death ultimately resulted from phthisis. Since that time complete extirpation has been frequently performed, and there are now fully one hundred recorded cases. The results, however, have not improved, and the operation has been abandoned by many who formerly performed and advocated it. The operation of partial laryngectomy stands so far on a much more favorable footing, and the brilliant results of Eugene Hahn and other German surgeons have established it as one of far less immediate fatality than complete extirpation, and affording average periods of immunity from recurrence even of the more serious forms of malignant disease, which promise to be almost, if not quite, equal to those provided by tracheotomy. The success of Hahn's operation recently performed in London on an English patient has naturally attracted much attention. Mr. Butlin very shortly afterward had a similar operation; and he was the first English surgeon to adopt the procedure; the result of his case was quite successful so far as immediate recovery was concerned. Recurrence must, in the nature of things, be always anticipated; and we have yet to see what sort of history our cases will have in this respect. It is earnestly to be hoped that care will be taken in the selection of subjects for this operation, as otherwise discouragement will be given to its performance where other circumstances would be favorable. It is indicated in unilateral and intra-laryngeal epithelioma, and in recent non-infiltrating sarcoma. It is useless in pharyngo-laryngeal epithelioma, in which the larynx is invaded from the pharynx, and whenever there is implication of the cervical glands and structures adjoining the larynx. It is always possible, if on division of the thyroid cartilage the disease is seen to have extended beyond the limits suspected by prior examination, for the surgeon to desist from removal and to be content with having performed tracheotomy.

Carbolic Acid in Typhoid Fever.—Professor Bartholow still continuus to advocate the use of carbolic acid in typhoid fever. He states that no form of treatment has, in his hands, been so successful. It modifies the disturbances of the intestinal tube, reduces temperature, and promotes quiet. Two drops of a solution consisting of equal parts of carbolic acid and Lugol's solution, may be given every three hours.

For Erysipelas.—Professor Da Costa continues to strongly advocate and recommend the use of pilocarpine in robust plethoric subjects. It is of striking value, and better results can be obtained than from any other mode of treatment. The proper dose is gr. $\frac{1}{8}$ to $\frac{1}{6}$ of pilocarpine, or ℥ xx. of fluid extract of pilocarpus. Local means are not of much avail.

The Cold Affusion in Headache.—Sir Robert Christison, in his "Autobiography," bears emphatic witness to the efficacy of this treatment, citing in particular the case of his own mother, who suffered from headache of a peculiarly persistent character, and who cured herself effectually by the cold douche. It was the favorite remedy of the Romans, as may be inferred from more than one passage in the judicious compilation of Celsus: "Capiti nihil æque prodest atque aqua frigida" (Nothing is so beneficial to the head as cold water), Lib. i., c. 4. Again (Lib. i., c. 5), when touching on the various inflammatory affections of the head and its cavities, he says: "Usus aquæ frigidæ prodest iis etiam quos assidue lippitudines gravedo, destillationes, tonsillaque male habent" (The cold affusion is of benefit to those also who suffer from chronic ophthalmia, from cold in the head, from catarrh, and from inflamed tonsils). Again, the lassitude and headache induced by the scirocco (*auster*), to which the British resident on the Mediterranean is so subject, and which no amount of acclimatization seems to lessen, has its appropriate remedy in cold water: "Præcipue omnibus eo auxilis utendum est ubi gravius cœlum austri reddiderunt" (This remedy is of especial advantage to all when the atmosphere has become heavy by the scirocco), Lib. i., c. 5.

Indications for the Use of Nitro-glycerine.—Dr. Trussewitsch, in an instructive paper on the use of nitro-glycerine, published in the *St. Petersburger Medicinische Wochenschrift*, points out that the value of this drug in various affections—angina pectoris, migraine, and neuralgia (which he describes as angioneuroses), as also in sea-sickness, some forms of anæmia, faintness, palpitation, and other diseases—depends upon the existence of an irregular distribution of blood, which condition may be inferred from a certain degree of pallor of the skin, especially of the face, often coexistent with a weak pulse and a small, rigid radial artery, which frequently is situated at some depth. When, on the other hand, headache and neuralgia occur in patients with chronic congestion of the subcutaneous veins of the face, nitro-glycerine is to be avoided; and similarly it is of no use in asthma, when the face is reddened in consequence of emphysema. If, however, a pale face exists with angina pectoris, migraine, giddiness, shock, toothache, or sea-sickness, the best results may be looked for by giving nitro-glycerine. The regulating effect of the drug exercises an influence over the congestion of internal organs similar to that brought about by bloodletting; and in these congestions, whether of lung, brain, or kidney, when they are of a temporary character, the pulse is generally found to be slow and of low tension—a fact which, as the author remarks, is sufficiently well known in reference to the fever-free periods of acute hyperæmia of the lung and kidney. Dr. Trussewitsch lays down as a rule that the condition of the pulse is the best indication for the employment of nitro-glycerine, and the most trustworthy guide as to the dose with which to commence the treatment. The smaller the radial artery is, the more rapidly it dilates under the action of the drug, and the less the secondary effects proceed; on the other hand, the fuller the pulse with a distended radial artery, the less it is affected; and finally, the softer the artery, with a weak pulse, the greater the secondary, and the less the general, effects. Single-drop doses of the one per cent. solution are sufficient in cases of small pulse, but with a full pulse it will be found that the full effects cannot be produced with less than two-drop doses. When there is a soft artery with a weak pulse, subnormal doses only should be given—a quarter to half a drop. After the trial dose is given, the patient's sensations of pulsation and pain in the head, as well as the distention of the radial artery under the finger of the physician, will be the guides for increasing the dose. The author finds that the best modes of administering nitro-glycerine are the simple dropping of the solution on the tongue, and by means of tablets; much less satisfactory results were obtained when given mixed with water.—*Lancet.*

Bright's Disease without Albuminuria.—At a recent meeting of the Société Médicale des Hôpitaux, M. Dieulafoy, who has already drawn attention to a form of Bright's disease in which there is no albuminuria, communicated the details of a case which had been verified by post-mortem examination. The patient was a man of sixty-three, suffering from headache and dyspnœa. Neither alcoholism nor syphilis were detected. Dyspnœa dated from several months back, and was characterized by attacks of oppression of a character differing from those which occur in asthma and emphysema. There was slight transient œdema below the malleoli; no albumen in the urine. Soon after admission, the patient was attacked with violent delirium and fever. Albumen was then discovered in the urine, and death took place on the eleventh day. The two kidneys presented characteristic lesions.—*British Medical Journal.*

Nephrectomy for Scrofulous Disease.—A successful case of removal of the kidney for scrofulous disease was brought before the Glasgow Medico-Chirurgical Society by Dr. Clark, one of the surgeons of the Royal Infirmary. The patient, a married woman of twenty-six, had gradually developed the signs of abscess in the left loin, and as the urine contained pus and epithelial débris, this was diagnosed as being a renal abscess. The kidney was incised in January, 1886, and about a pint of pus evacuated, but the sinus continuing to discharge and other abscesses forming in the kidney, extirpation of the organ was decided upon. This was done in August last, by the lumbar incision, without any difficulty, the only incident worthy of note being the slipping of the ligature at the time of separation of the kidney from its pedicle. The patient made rapid recovery, and is now in perfect health, with a normal excretion of urine. Dr. Clark specially dwelt on the importance of the evidence obtained by the use of the ureteral catheter, as showing the other kidney to be sound, and showed that in the female the introduction of a catheter into the ureter was safe, easy, and satisfactory. He referred to the statistics of extirpation for scrofulous disease, and objected to the conclusion of Gross that the ventral was safer than the lumbar incision in such cases.—*The Medical Press*, January 26, 1887.

Urticaria.—Lassar cuts short the duration and reduces the frequency of violent attacks of urticaria by twenty-four-grain doses of salicylate of sodium, repeated every two hours until three doses are taken. It is certainly well worthy of a trial, as the trouble is undoubtedly at times a very stubborn, not to say serious one

Cod-liver Oil in the Nervous Affections of Children.—Dr. Frederic F. Andrews (*The Practitioner*, December, 1886) urges the use of cod-liver oil in the various nervous affections of childhood. He says that if we take a general view of the diseases which belong to this early period of life, this period of growth and development, we shall be struck by the one special character—they are all more or less convulsive, either as general convulsions, the commonly recognized convulsion-fit of infants, or the convulsive inspiration of laryngismus stridulus, or the dyspnœa of what has been called "rickets of the chest," or later on of chorea and epilepsy. All these have probably their origin in the great function of its young life; it is struggling, striving with all its might, to grow, all its energies are concentrated on this one necessity, and it is often carrying on the battle under adverse influences. He offers the following propositions: 1. In the process of the growth of new tissues there is a great expenditure of nerve-power, and also a disappearance of heat, which assumes some form of potential energy. 2. The exhaustion consequent upon this expenditure first shows itself at the age of three or four months (before dentition) in a nervous headache which is apt to be mistaken for the first stage of meningitis; later on, if dentition is going on easily and rapidly, that is to say, if the gums are full instead of showing one tooth at a time, we may have laryngismus stridulus; still later, what is called "rickets of the chest," but which is probably a nervous asthma from exhaustion of the pneumogastric and respiratory tract, supervenes; and subsequently, when the growth of the limbs takes place, the great strain is on the spinal nerves, and the child is liable to chorea. 3. All these diseases are the result of the exhaustion of special nerve-centres engaged at the time in some new and special development, which development takes place as it were in successive segments or portions. In the first three months the special senses are evolved, and we have pseudo-meningitis; if these symptoms are treated wrongly convulsions will ensue, and death will seem to justify the diagnosis. Between the fifth and ninth months the teeth appear, and we have laryngismus stridulus. From nine to twelve months the stomach and digestion are developing, and we have a form of asthma called "rickets of the chest." Afterward the limbs grow markedly, and we have chorea. All these troubles he takes to be the result of nerve-exhaustion. 4. The disappearance of heat and expenditure of nerve-power are best met by the exhibition of cod-liver oil. The starchy and saccharine foods may have sufficed for the formation of the fatty tissues (the child may be quite fat), but are not serviceable for supplying nerve-power and for replacing the heat which disappears during growth. For these purposes it is necessary to exhibit some animal oil. 5. The due exhibition of cod-liver oil will, therefore, not only cure these ailments, but should in a great measure prevent them.

Different Methods of treating Cervical Catarrh.—Dr. L'voff, of Kazan, has reported in the *Meditsinskoe Obozrenie* a number of observations made on the comparative value of different methods of treating catarrh of the cervix uteri. The total number of cases was 82. Of these, 36 were treated by mechanical scraping of the mucous membrane, 18 by means of powerful caustic applications, and 28 with weak caustics. The method of applying the weak caustics was, after washing out the vagina with warm water or a solution of boracic acid, to swab the cervical canal with tincture of iodine or with a ten per cent. solution of chromic acid. This was done once a week, plugs soaked in glycerine of tannin being also used every other day. The strong caustic application consisted of a bougie made of sulphate of zinc and alum fused together. This was allowed to remain in the canal till it had all dissolved, which took place usually in one or two hours. Afterward the mucous membrane presented a white appearance, due to the eschar. This fell off in five or six days, during which time warm vaginal douches were administered and plugs of glycerine and iodoform inserted every alternate day. In the cases treated by scarification an iodoform and glycerine plug was left in for twenty-four hours, and the patient was then sent home. The results of these different methods of treatment were that the mild caustics ultimately effected a cure, but required at least two months to do so; while the severer methods—that is to say, the fused zinc and alum, and the scarification—produced a permanent cure in about a fortnight. The author adds that no unpleasant symptoms were caused by either the caustics or the scarification in any of the eighty-two cases.

Simple Method of estimating the Effects of Respiration.—MM. Hanriot and Ch. Richet have described a method of measuring the oxygen inhaled and absorbed, also the carbonic acid formed, during respiration, which is much more simple than the usual method by weighing, and is adapted for carrying out at the bedside. A gas-meter measures the volume of air inhaled, and a second, that of the air expired; this air is then passed through potash, and subsequently through a third gas-meter. The difference between the second and third meters, of course, gives the carbonic acid formed, and the difference between the first and third, the oxygen absorbed.

The Cholera in Valencia in 1885.—We have received a very voluminous report, presented to the Ayuntamiento of Valencia, concerning the epidemic of cholera which occurred in that city in the summer of 1885. The work has been prepared with great care, and is a valuable addition to the literature of cholera. Numerous maps and plans add to the usefulness of the report.

Crotalus or Rattlesnake Poison—Its Sphere of Action and Usefulness.—Dr. Alfred Drysdale, in the *Medical Press and Circular*, December 8, 1886, presents a scholarly article on this subject. Regarding the therapeutic application of crotalus he says: "The practical value of crotalus in the treatment of disease has been abundantly proved, if clinical experience is to be accepted as proof, which in the face of the great *post hoc propter hoc* dilemma must be considered as doubtful. All that can be said in this respect is that the data forth-

coming are as reliable as those which have established the reputation of many of the reigning therapeutic favorites. The main application of this remedy is in the pernicious fevers, where the whole mass of the blood is vitiated, probably as a consequence of the diminution or loss of vitality of the protoplasm composing the leucocytes. A condition is well known in cases of almost all the fevers, and in pneumonia, where the patient is so reduced in strength that he can only lie on his back, usually with eyes open; the hands are seen to be tremulous and in incessant motion—what is called carphology and subsultus tendinum being present—the tongue is dark-brown, especially in the centre, and conveys to the sensation a roughness like that of a brick; the pulse is extremely rapid (140, 150, or more) and irregular; muttering delirium may be present, but the patient is evidently too weak to utter loud sounds. This condition, known as the 'typhoid state,' whether supervening upon a continued fever, pneumonia, or mere senile asthenia, is well and successfully treated by drop doses of solution crotalus, 1 in 100, repeated every two hours. Most medical men have met with a condition of body, usually at the end of an organic complaint of long standing, such as Bright's disease, phthisis, mitral disease of the heart, etc., but sometimes merely from age added to want or deficiency of essential ingredients of the food even in young people. The patient at once strikes spectators as having a wretched aspect—the face is waxy and transparent, chlorotic in hue, restless in expression, the eyes bleared and sunken, the lips white and covered with sticky exudation; slight injuries, pressure of clothes, etc., are apt to produce ecchymoses; purpuric rashes, indolent suppurations, or even gangrene, are common. Extravasated blood is liable to make its appearance in almost any tissue, organ, or secretion of the body. Such a condition, whether following upon organic disease or due only to insufficiency or improper quality of the food (scurvy), is well treated by drop doses of crotalus solution (1 in 100); the blood is gradually brought to a healthy condition, where this is possible, and in other cases amelioration and prolongation of life may be confidently looked for."

Bone-Marrow and Pernicious Anæmia.—Dr. H. Chr. Geehinnyden reports (*Virchow's Archiv*) the results of his very extensive researches upon bone-marrow (two hundred and fifty cases), and comes to the conclusion that it is concerned in the production of pernicious anæmia.

Fever Hospitals in Paris.—The sanitary committee of the municipal council of Paris has recommended that two fever hospitals be erected in two extremes of the city for the accommodation of patients suffering from whooping-cough, measles, scarlet fever, or diphtheria. Each hospital is to have separate pavilions for each of these diseases.

Deaths from Ear Disease.—Dr. Ariza, writing in *El Dictamen*, asserts that every person who has had suppurative otitis media, dating from infancy, dies from the consequences of this affection before or during early adult life. Death in these cases results from caries, pyæmia, thrombosis of the cranial sinuses, meningitis, encephalitis, or abscess of the brain.

Chlorodynomania.—A husband lately complained at the Westminster Police Court that his wife, aged thirty, would drink three or four bottles a day of chlorodyne. She was, he alleged, entirely destroying her own mind, and ruining him in pocket.

The Australian Medical Association has presented a petition to the government asking that vaccination be made obligatory; that no person be allowed to practise medicine who has not had some hospital experience; and that a pension be given to the widows and orphans of medical men who have died in the discharge of their duty during an epidemic.

The Elastic Ligature for Uterine Fibroids.—The removal of uterine fibroids by means of the elastic ligature having been recently adopted by Professor Slavyanski in four cases, a paper has been published by one of his pupils, Dr. Zhabotinski, dealing mainly with the history of this method of operating. He has collected accounts of 216 cases, of which 151 are British (44 being Dr. Robert Lee's), 27 French, 20 German, 10 Russian, 5 American, and 3 Italian. Of these, 18, or 8.3 per cent., proved fatal—8 from peritonitis, 3 from septicæmia, 3 from exhaustion, 1 from pleurisy and peritonitis, 1 from meningitis, 1 from tetanus, and 1 from an accidental disease. In 12 of these, death occurred before the tumor came away, and in the remaining 6 after separation had taken place. The author thinks that the opinions of West and McClintock on the dangerous character of this method of procedure were formed on the results of too small a number of cases; and that as most of the published cases occurred in pre-antiseptic times, the danger with modern methods may be looked upon as very slight. The mode of procedure which Professor Slavyanski adopted, and which in Dr. Zhabotinski's opinion is the best, is to cut away the tumor after the elastic ligature has been applied to the peduncle. This seems to have given the best results, even before the days of antiseptics. The main indications for the elastic-ligature operation are a pedunculated condition of the tumor, an accessible situation, and a disposition to hemorrhage.

Cod-liver Oil.—M. Carles, Professeur Agrégé at the Faculty de Médecine of Bordeaux, has recently re-affirmed that the cod-liver oil which is lightest in color is the purest and the most easily assimilated. The deep color frequently seen in cod-liver oil is owing to more or less putrefied livers having been used.

The American and the British Medical Association.—Dr. Davis has returned from the Brighton meeting of the British Medical Association full of admiration and kindly feeling toward his professional brethren in England, and speaks highly of the cordial reception with which he met, and of the opportunities which were afforded to him and his brother representatives of offering a welcome to intending visitors at the approaching congress. He does not, however, appear to have gathered a very clear idea of the constitution of the Association, for, oddly enough, he speaks of the Council of the British Medical Association as being an imperfectly representative body, while, on comparing the constitution of the English with the American Association, it is very easy to see that the British Medical Association is by far the more democratic in principle, and more thoroughly representative in character, seeing that its Council appears to be elected wholly by the branches, and its presidents by the local profession in each district in succession in which the annual meetings are held. The presidents of the meetings so elected by the common vote of the profession are apparently the only permanent members of the Council. On the other hand, the American Medical Association is reproached with being very "cliqueish" in its constitution, being made up of delegates from county medical societies, which are often controlled by small knots of men, and are by no means, in all cases, widely representative. It is, however, natural that Dr. Davis should prefer a constitution which he took so much part in framing to that of any other body. It cannot be said, however, that the American Medical Association is so prosperous or widely representative, or so robust as its friends could wish. It has a relatively small membership. Its journal has as yet but a very secondary position in literature, and the Association cannot be said to exercise anything like the influence which it would do if it were larger, more comprehensive, and more national in character. Its aims are high, its principles sound, its finances secure; its development is alike to be desired and anticipated.—Correspondent of *British Medical Journal*.

Syphilis and Pregnancy.—A series of very remarkable clinical observations on syphilis in pregnancy have recently been made by M. Hirigoyen, at the Maternity Hospital in Bordeaux, from which he concludes that, from an obstetric point of view, both abortion and natural labor take place in syphilitic patients exactly as in healthy women. In certain exceptional cases, however, difficulties attributable to syphilis may arise, such as hemorrhage from partial adherence of the placenta, rigidity of the os, etc. Finally, women suffering from primary or secondary syphilitic lesions in the genital organs are rather predisposed to puerperal accidents, and requre more attention on the part of the attendant than other women. The following is a summary of the observations, which extended over a period of two years: 1. In the lying-in wards, in Bordeaux, the proportion of syphilitic to other patients was five per cent. 2. Five-sixths of them were unmarried. 3. Syphilis in a pregnant woman tends to bring about premature labor. 4. The duration of the disease seemed to have a very decided influence. 5. In eight cases of pregnancy in syphilitic women who had had the disease for one or more years, only two children were born alive, and these were very puny. 6. In twelve cases, in which the mother had contracted the disease during the first four months of pregnancy, the fœtus was in every case stillborn. 7. When the mothers had become affected between the fourth and the sixth months of pregnancy, the fœtus died in about half of the cases. 8. When syphilis had been contracted during the three last months of gestation, the proportion of living children was a little more than one-half—four out of seven. 9. Out of thirty-three cases of pregnancy in syphilitic women, living children were born in eight. 10. Syphilis may give rise to difficulties during labor, and also to subsequent complications, but this is rare. 11. To be effectual, antisyphilitic treatment should be administered from the very beginning of pregnancy, and continued throughout. The treatment should be perseveringly carried out, in order to prevent accidents in future pregnancies.—*British Medical Journal.*

Drugs in the Management of Cases of Enlarged Prostate.—In the course of a paper in the New York *Medical Journal*, Dr. F. W. Rockwell says: "Three drugs are at the present time given with the belief that they exert a direct influence on the disease. I name them in order of their value so far as I have personally been able to judge of their effects. They are ergot, potassium iodide, and chloride of ammonium.

The Malthusian Medical Law.—Statistics show that, while the population is increasing annually at the rate of less than two per cent., the annual increase of physicians is five and a half per cent., a condition that cannot exist without change through many centuries without one inevitable conclusion—a population composed entirely of physicians.

International Health Congress at Vienna.—The Executive Committee of the Sixth International Health Congress, which is to be held at Vienna from September 26 to October 1, 1887, has already issued its preliminary programme. The Congress is under the patronage of the Hereditary Prince of Austria, and the following are honorary presidents: The Ministers Taaffe and Gautsch, Statthalter Possinger, Landmarschall Kinsky, and the Bürgermeister of Vienna, Herr Uhl. The president of the Congress is Hofrath Professor Schneider. The council consists of the vice-presidents, Hofrath von Tuama, Professors Böhm, E. von Hofmann, and many other notabilities. The subscription of each member of the Congress is ten florins. Each member who announces two months beforehand his intention of taking part in the Congress, will receive a copy of the reports (*Expositions-referate*) which appear before the meeting of the Congress, and also a copy of the general report, which will be published afterward. At the two general meetings only lectures will be delivered; at the sectional meetings there will be discussions of the reports. Papers which have already been published, and which have already been read before scientific societies, will not be received.

The Relation of Physicians to their Medical Supplies.—The following is from the January, 1887, *Ephemeris*, by Dr. Squibb: "There are a large number of physicians who, for both therapeutics and materia medica, depend largely, if not mainly, upon the travelling salesmen and their pamphlets and lists, and on the advertising pages of the medical journals. The relations of this class to their supplies are most simple and most favorable. They come in very direct and very close contact with the sources of their supplies, and have much less trouble than any other class of artisans. With others, smarter, more ingenious, and more plausible than they to think for them, and then to apply vigorous mercantile principles to their wants thus suggested for them, they have the least practicable amount of thinking for themselves to do in regard to their remedies and the novelties of the day, and, therefore, as they argue, more time to think of and study out their cases. To this class the ready-made prescriptions in the form of beautifully-colored and coated pills, or palatable solutions and mixtures, do not appeal simply as gratifying various degrees of laziness, or indisposition to think for themselves, but they present themselves as true labor-saving devices, skilfully prepared for the over-worked ability to use them, and as giving more time for the higher and more scientific researches of the profession."

Proprietary Tonics and Bitters.—The analysis of the Massachusetts State Health Board shows that almost all the various tonics, bitters, and other temperance drinks contain from eighteen to fifty per cent. of alcohol.

"A Book for Every Woman," by a woman doctor, is now receiving the castigations of our Western medical contemporaries. It is written by a woman, who, graduating in 1881, speaks in 1886 of the numerous cases met with in her long professional career. It advises against abortions, but tells how conception can be prevented, and it has been editorially indorsed by the St. Louis *Evangelist* as a work to be put in every woman's hands. Of prevention of conception she says: "Some of the appliances sold for this purpose are a sure prevention by mechanical interference. If the material is pliable, the only positive injury is from preventing complete interchange of magnetism, and the harm may be considered more a negative than a positive one." Again: "By some also a theory called sedular absorption is advanced. In this, intercourse is had without culmination. No discharge is allowed. People practising this method claim the highest possible enjoyment, no loss of vitality, and perfect control of the fecundating power." This is the theory on which Guiteau was fed while living in the Noyes Free-love Community.

The Last of the Medical Maidens.—The thirty-eight female students who have entered their names for the next examination will be the last to be admitted to the Russian School of Medicine for Women, that establishment being about to be closed after an existence of fourteen years.

The Saturating Treatment for typhoid fever is being popularized in the columns of the *Southern Practitioner*. Dr. G. W. Renfro concludes an article on treatment as follows: "Saturate your patient with turpentine and pickle him in acid, and he will not die of typhoid fever." Dr. J. W. Grace offers, as an amendment: "Saturate your patient in turpentine, pickle him in acid, smooth him out with opium, and salt him down with quinine, and he cannot die."

LOCAL TREATMENT IN DIPHTHERIA.[1]

BY C. E. BILLINGTON, M.D.,

NEW YORK.

OF the two great divisions of the therapeutics of diphtheria, the constitutional and the local, each is of vital importance as the essential complement of the other. It is, therefore, from no disposition to ignore the former that the latter is chosen as our present topic, but rather from the impossibility of profitably considering both within the limits of a single paper and a single discussion. The latter has been chosen instead of the former, because, while there is certainly not complete unanimity in the profession in respect to the one, there is still greater diversity of views concerning the other.

It is not the object of this paper to present new therapeutical methods, nor any new array of clinical facts, but rather to inquire, in view of clinical facts already in our possession, what objects may be rationally aimed at in local treatment, what kinds of methods are suitable, upon what principles their utility depends, and what are the limitations beyond which their employment must be futile or injurious.

The factors to be dealt with in diphtheria are, first, a *specific poison* or contagium, which first causes the disease and is being constantly reproduced so long as that continues. Its precise nature and mode of propagation are not known, and need not now be discussed. That this poison acts by direct local contact or implantation in some cases is beyond question. The fact that the disease usually occurs in limited and non-symmetrical areas in the outer avenues of entrance of inspired air, the nasal passages and the oral and pharyngeal cavities, is strongly suggestive of the probability that this is its mode of reception in the great majority of cases. This consideration in turn suggests the probability that antiseptic treatment of those regions, in those who are exposed to the contagion or the epidemic influence of the disease, may be of prophylactic utility. No facts, however, are known to the writer which bear upon this point with sufficient definiteness to be worthy of mention.

Second, *inflammation.* This, if pre-existing from other causes, may invite the invasion of the disease. It is an essential part of the morbid process in the disease. Its extent and intensity are usually, in its earlier stage, in proportion to the severity of the disease. Its aggravation by any extraneous cause tends to the aggravation of the disease, and it ceases only with the cessation of the disease. From these facts result important and generally recognized therapeutical indications; namely, first, the curative treatment of pharyngeal or nasal catarrhal inflammations during the endemic or epidemic prevalence of diphtheria as attended with especial danger, and, second, the employment of the earliest and most efficient possible antiphlogistic measures, local as well as general, after the invasion of the disease, in the hope of mitigating its intensity and limiting its extension; also an important contraindication, namely, that of all local agents or methods which are liable to cause irritation.

Third, *membranous exudation.* This is a usual and probably an invariable result of diphtheritic inflammation. It varies greatly in extent, in texture and density, in thickness, in the depth to which it penetrates the mucous membrane, or even its subjacent tissues, and in its persistency and duration. It is a most important and formidable element in the disease, not only from the fact that in certain locations it interferes mechanically with deglutition and respiration, but even more so because in any situation it shuts in beneath itself the poison which is there being produced, prevents its being diluted and washed away by the saliva or the mucous secretions, or by therapeutical agents employed for that purpose, thus favoring its absorption. The obstacle which it thus presents to local antiseptic measures varies, of course, with its extent—its density, its thickness, and its depth being, in some cases in which these are very great, practically an insurmountable obstacle to efficient antisepsis. Fortunately, in the majority of cases these are not so great that something may not be effected by appropriate measures, which will be presently referred to, through transudative action.

But, formidable as are the dangers attending the presence of diphtheritic membrane, this presence is often to be preferred as the less of two evils, the greater evil being its premature removal. If left to itself it becomes detached if the patient survives, after a longer or shorter period, a sufficient reparative process having usually preceded and prepared the way for that detachment to enable it to take place with comparative safety. It is true that it is often, even under those circumstances, replaced by a second formation of membrane, but this latter is usually less formidable and of shorter continuance than its predecessor. Very different is it when, by injudicious haste on the part of the physician or some unfortunate effect of the crying or struggling of the patient, the membrane is torn off before that point in its history is reached. There is liable to be an immediate increase of inflammation, with symptoms of shock and general irritation, and the exudation which ensues is apt to be more serious and extensive and the absorption of poison greater than before.

It is often the case that one portion of a membranous patch which is comparatively shallow and superficial becomes detached, while another portion, which is deeper, still adheres. There is then great temptation to hasten the cure by its removal; but, on the contrary, this is, as a general rule, to be carefully avoided, as attended with danger. The utmost gentleness in the giving of food and medicines should then be practised. The writer has more than once seen the whole aspect of a case that was progressing favorably suddenly and fatally changed for the worse by an opposite course, or by some unfortunate accident, and indeed has long ago learned to look upon the period of the detachment of deep membrane in grave cases of diphtheria as a dangerous one.

The destruction of diphtheritic membrane by caustic applications, and even by the actual cautery, has been practised and advocated by some, and it is difficult to read the therapeutical literature of diphtheria, from Bretonneau down to recent medical journals, and avoid the conclusion that in some cases the disease has been arrested at an early stage by such procedures. The theory of their action is that, by destroying the specific morbid elements in the local disease, they substitute therefor a simple ulcer. This is probably the true indication for treatment in cutaneous diphtheria; but it need

[1] Read before the Section on Practice of the New York Academy of Medicine, March 15, 1887.

hardly be remarked that in the widely different conditions existing in diphtheria of the mucous membranes of the pharynx and nares the safe accomplishment of this object by such formidable agencies, must for obvious reasons be, in a large proportion of cases, difficult or impracticable from the impossibility of making their action at once sufficiently extensive and thorough and sufficiently limited. It is doubtless for this reason that the employment of such agents in the local treatment of diphtheria has been by the great majority of the profession discarded. Yet the possibility of their safe and successful use in certain favorable cases at an early stage of the disease, by sufficiently accurate methods of application and with the exercise of due caution and skill, is a topic worthy of consideration.

But leaving out of the question the dangers attending the employment for this purpose of violent avulsion or corrosive applications, the important inquiry remains, Would the rapid destruction of diphtheritic membrane, even by means which are in themselves innocuous to living tissues, were such means in our possession, be, as a general rule, advantageous or detrimental? This inquiry can, of course, be finally answered only by experience, but some considerations make it seem probable that the answer must be that in many cases it would be detrimental. It must be remembered that diphtheritic membrane, hostile as its presence is to our therapeutical endeavors, yet performs one important function of the epithelium at the expense of which it exists—that of protecting the tissues beneath it from external irritation. It must be remembered also that the importance of this protection must be in direct proportion to the depth to which the membranous exudation extends. In the numerous cases in which it is comparatively superficial, involving only the most external epithelial layers, its removal might often be attended with no very serious dangers. But these are the cases which tend to recovery, and are of comparatively transient duration under any rational mode of treatment. But in those cases in which the necrobiotic and exudative process has penetrated deeper, the conditions which would follow its rapid removal must be much more serious. In its place we should have a denuded and highly sensitive surface in a state of inflammation and the tissues immediately beneath it permeated with the specific poison of the disease, to which the very impact of air or of the perverted mucous secretions or the mechanical movements of deglutition would be painful and irritating. It seems inevitable that the sequel should often be intensified diphtheritic inflammation, with all its deplorable train of local and remote results.

It seems probable, then, that, undesirable as is the presence of diphtheritic membrane, its rapid and entire destruction by any means whatever is not, as a general rule, an end to be aimed at in treatment. What, then, are rational objects of endeavor in dealing with this most formidable element of the disease? They would seem to be the following: First, and as a general rule, to effect its softening and thinning by means of gradual and non-irritating solvents, thus diminishing the obstacle which, by its thickness and density, it presents to antiphlogistic and antiseptic treatment until such time as the subsidence of inflammation beneath it and the reparative processes of nature shall result in its complete and safe detachment; second, in exceptional cases, in which its rapid removal or disintegration is urgently demanded, to effect that object, if it be practicable, by such means as will cause the least irritation to the living tissues. What is lacking in brilliancy to this therapeutical programme will probably be more than compensated in the aggregate of cases by satisfactoriness of results as compared with those of more hasty and aggressive methods. In 34 cases that recovered out of 38 that were treated in accordance with the principle now advocated, as was reported by the present writer in this place seven years ago, the duration of membrane was stated to be as follows: Two of two days, 2 of three days, 4 of four days, 5 of five days, 6 of six days, 2 of seven days, 1 of eight days, 1 of ten days, 1 of twelve days, 2 of thirteen days, 3 of fourteen days, 1 of fifteen days, 2 of seventeen days, 1 of twenty-two days, and 1 of twenty-seven days. Perhaps it would be well if it were more generally appreciated that the true object of treatment in diphtheria is not so much to cure the disease as to bring our patients through it alive.

Fourth, the *absorption into the circulation of poison* from the seat of the local disease, resulting in the contamination and impoverishment of the blood, and a variety of organic morbid changes which need not now be enumerated.

The error that constitutional symptoms peculiar to diphtheria usually occur before membranous exudation takes place is one which has been too long perpetuated and too often repeated. It is not true that the initial or ante-membranous stage of diphtheria differs in any of its clinical aspects from the corresponding stage of various other forms of angina. There is not in the one a higher or a lower temperature than in the others; there is not greater or less nervous disturbance; there is not greater or less frequency of an antecedent chill or of a prodromic period of depression.

The absorption of poison undoubtedly begins, as a general rule, with the beginning of membranous exudation, and occurs, to some extent, in every case, so that the disease, although probably in the great majority of cases a primarily local one, becomes at an early period also constitutional. It is important to note, however, that the rapidity and amount of constitutional infection vary directly, as a general rule, in proportion to the extent, and more particularly the depth, of the membranous exudation. It is also true that it varies inversely in proportion to the efficiency with which local antiseptic treatment is employed. This fact the writer has seen demonstrated in many cases. In a paper which he had the honor to read before the Academy in 1876, and which is contained in the "Transactions" of the Academy for that year, were presented the results of many observations confirming this statement, in a series of one hundred and seventy-nine cases. These observations, which were in accordance with many earlier and later ones by others, may be briefly summed up as follows: Many cases of diphtheria, in which local treatment was early and persistently employed, continued throughout their course to exhibit little or no evidence of constitutional poisoning. In many others, in which evidence of that condition already existed, it disappeared or notably diminished under the employment of such treatment when that was commenced before the effects of the poisoning were already irremediable. Finally, even those cases in which the treatment failed to prevent fatal diphtheritic toxæmia were, in reality, illustrations of the truth of the principles on which its utility is based, being invariably those in which, for various reasons, either in the nature of the cases themselves or the attendant circumstances, it could not be or was not efficiently employed. Moreover, these fatal cases by toxæmia were so few in proportion to the whole number and to their usual ratio of occurrence as to leave no reasonable doubt of the general efficacy of this therapeutical measure in fulfilling the important purpose for which it is employed. In a second paper, read before the Academy on March 4, 1880, and published in THE MEDICAL RECORD of March 27th of that year, which paper was based on a series of forty unquestionable, fully attested, and fully described cases of diphtheria under the most efficient possible application of this method of treatment, it was stated that of the whole number of cases only one terminated fatally from the effects of toxæmia, and that one under such peculiarly unfavorable circumstances (which were described) as to make it one of the exceptions which "prove the rule." The following statement was also made: "The urine was tested for albumen in fourteen of the foregoing cases, always when the disease had continued for some days, and usually when it was at its

height. That it was not tested in all was simply because some of the patients were so very young, and from negligence in other cases. In only one (Number 11) was any trace of albumen found." That exceptional case was typical, and the following brief outline is therefore condensed from the full account of it in the paper referred to. In that case a patch of particularly deep and dense membrane on the posterior side of one tonsil persisted after the rest had disappeared. On the sixth day, urine scanty and heavily albuminous; marked symptoms of uræmic poisoning. This condition continued during the two following days. On the ninth day the patch of membrane had disappeared. On that day the urine was considerably increased in quantity and contained a smaller proportion of albumen, the general condition of the patient being improved and encouraging. On the tenth day the membranous patch had re-formed. Urine again scanty and heavily albuminous; return of the previous unfavorable symptoms. This condition of things continued with gradual improvement for eight days more, during which the membranous patch persisted. At length it was again and finally detached, and the albumen rapidly disappeared.

Since, as has already been remarked, a certain amount of toxic absorption probably occurs in every case of diphtheria, and since, nevertheless, many patients recover from the disease without permanent injury, it follows that nature is capable of tolerating the presence of, and of eliminating a certain amount of the absorbed poison. The facts that have just been referred to show that local antiseptic treatment, by removing the poison-charged secretions and promoting osmotic interchange of fluids through diphtheritic membrane, may so far diminish this absorption as to keep it within the limits of that amount in a large proportion of all cases. From this fact results the therapeutical indication which is probably the most important one in the treatment of diphtheria. The obstacles and difficulties which a small proportion of cases oppose to the fulfilment of this indication constitute its most perplexing and deplorable limitation.

Fifth, the *emanation of poison from those affected with the disease*, and the consequent infection of others.

The records of 201 dispensary cases included in the papers just referred to show that 2 occurred together or consecutively in the same family in eighteen instances, 3 in five instances, and 6 in one instance, while 144 were solitary cases subsequently to the commencement of antiseptic treatment, although not a few of them had been preceded by other cases under other treatment. Considering that these cases occurred in tenement-house rooms, where little or no separation of the sick from the well was practicable, and that the majority of them occurred during the great epidemic in that district of 1875, the supposition seems not unreasonable that the amount of infection resulting from them was in some degree limited by the treatment employed. This seems all the more probable from the fact that only two adults among all the parents and others who took care of them contracted the disease.

From the foregoing considerations, it appears that the principal objects of local treatment in diphtheria are the following: First, to subdue inflammation; second, as a general rule, to which there are exceptions, to effect the gradual and superficial softening and thinning of false membrane, rather than its rapid and complete removal or destruction; and third, by antiseptic measures to minimize the absorption and dissemination of poison.

It is next in order to inquire what are the most suitable means for the accomplishment of these objects. This inquiry will probably be most conveniently made by considering the various methods of topical application, and, in connection with each, some of the remedies to which it is best suited.

First among these methods is that of *internal administration*, for the sake of local effect in the mouth and throat. This method has the advantages of simplicity and of ready and general availability, but as the remedies employed by it are usually selected for the sake of their constitutional effect as well, it belongs only in part to our present subject.

The frequent swallowing of water, milk, or any innocuous fluid is doubtless useful by diluting and washing away foul secretions. Ice and iced beverages have a well-known and valuable effect in the presence of acute inflammation.

Among medicinal agents the tincture of the chloride of iron and the chlorate of potassium undoubtedly hold the leading place in general use and estimation. Their action is too well known to require present remark. One or two points, however, in relation to the best mode of administering them are worthy of passing mention. Anyone can easily be convinced by his own sense of taste that the disagreeable acridity of the tincture of iron is pleasantly covered by glycerine when mixed with it in the proportion of one to eight, but that this is less perfectly effected by a smaller proportion of the glycerine. Children often appreciate this difference most keenly. Hence this formula is suitable in their cases: ℞. Tinct. ferri chlor., f ʒ j.; glycerinæ, aquæ, āā f ℥ j. M. et Sig.: A teaspoonful every hour. Remedies administered internally in diphtheria must, to have any valuable local effect, be given frequently, and the result of frequent struggles may be disastrous. Hence the importance of avoiding any unpleasant medication in this disease in the cases of young children can hardly be exaggerated.

Again, many diphtheritic throats, especially of young children, are in a state of such exquisite sensitiveness that tincture of iron in any combination whatever will cause local pain and irritation, and not infrequently reflex vomiting. Hence the writer has been accustomed to prescribe the chlorate of potassium separately in the mixture: ℞. Potass. chlorat., ʒij.; glycerinæ, f ℥ ss.; aquæ calcis, f ℥ ijss. M. A teaspoonful to be given in half-hourly alternation with the tincture of iron, but to be substituted for it whenever the latter shall produce any unpleasant effects. This has been found very valuable in the class of cases referred to. These may seem to some trivial details, but success in the local treatment of diphtheria often depends on careful attention to details and even minutiæ.

The experience of the writer accords with that of many others, that the tincture of iron is of positive value in the treatment of many cases of diphtheria, and in some is advantageously given in large doses, but has not been that it is essential to the successful treatment of most cases in which other appropriate remedies are employed.

Among other drugs which have been administered by this method, partly for local effect, bromine and the benzoate of sodium seem to have especial claims to mention. Almost incredibly good results from a system of treatment in which the latter was the principal agent were reported by Dr. A. Brondel in the *Bulletin Général de Thérapeutique* for November 15, 1886.[1]

Gargles occupy a large place in much of the therapeutical literature of diphtheria, notwithstanding the fact that a large proportion of all our patients are children too young to gargle. Even in older patients the frequent use of gargles is unpleasant and fatiguing and, moreover, in many cases inefficient from their not freely reaching the posterior part of the pharynx.

The washing of the throat and the application of remedies to it by means of a *syringe* is much more generally applicable, and is usually preferable to the preceding method. In some cases the throat has a tendency to fill up with tenacious and offensive secretions, which are locally irritating and greatly increase the danger of systemic infection. These may be readily dislodged and removed by syringing, not only from the anterior side of the soft palate, the tonsils, and the faucial pillars, but

[1] See THE MEDICAL RECORD, January 8, 1887.

from their posterior side as well, and with less pain and fatigue to the patient than are caused by gargling. An ordinary ounce or half-ounce syringe with a straight tip and a ring in the handle is a suitable instrument, and a solution of common salt, in the proportion of a drachm to the pint, an appropriate fluid for this purpose, though a great variety of combinations known as gargles may, of course, be thus applied.

But the recommendation of this method, which is, under proper restrictions, both efficient and safe, is accompanied with the grave responsibility of calling attention to its limitations and dangers, which are important.

The pharynx, with its abundant supply of very sensitive nerves, was obviously never intended by nature to tolerate rude manipulation or violent impressions of any kind. The effect of the violation of this law is shock, prostration of strength, and undesirable reactions both local and remote. There is great power of irritation in the impact of a stream of water thrown forcibly from a syringe. Hence the syringing of an inflamed throat should be done only with extreme gentleness, and not too frequently. Syringing the throat should never be practised when it contains diphtheritic membrane in the stage of partial detachment, as this is very liable to be torn up thereby with the results which have already been referred to. The writer saw, not long ago, a melancholy illustration of this danger. Syringing of the throat should, as a general rule, be employed only in those cases in which spraying is impracticable.

The fact that toxic absorption is particularly liable to occur in nasal diphtheria is established by general observation. *Syringing of the nasal passages* in that form of the disease has consequently been so long and so widely practised that arguments in behalf of its importance would be superfluous. There are, however, questions relating to the method of performing it, and to its limitations, respecting which there is less complete concurrence, and which are important enough to be worthy of consideration.

Simple as is this procedure it has often been made, by bungling methods, or want of method, very formidable and distressing. Its principal difficulty arises from the resistance which it usually provokes in young children, whose struggles, if not properly controlled and prevented, may be a formidable obstacle to the operator and exhausting to themselves. This difficulty will be found to vanish if the following brief and simple directions are followed, which the writer takes the liberty of repeating from the first of the papers to which reference has previously been made: "The child should be seated across the lap of one person, who should secure his hands. Another should stand behind him and support the back of his head (which should be inclined forward) against his breast, holding it firmly with a hand on each side. A third can then easily make the injection into the nostrils. The more strength and decision are manifested, the less is the child likely to struggle." Any small syringe, such as was just described, will answer in expert hands—and this task should never, if it can possibly be avoided, be entrusted to any others. Tepid salt water is a suitable fluid, but any similarly unirritating and antiseptic one would probably be equally appropriate. The fluid should be thrown with force enough to cause it to return partly by the other nostril, and partly by the throat, if the nasal passages are pervious. If they are not so, perseverance in the use of gentle injections is, as a general rule, safer than the use of very forcible ones. The remarks that were made as to the irritating and prostrating effect of violent injection of the pharynx, apply also to that of the nasal passages. The injections should be repeated sufficiently often at each *séance* to effect, if possible, a thorough cleansing.

A very important question remains. How often shall this process be repeated? In both of the papers previously referred to it was stated that it was in all of the cases therein included performed only by the writer himself, or the physicians who assisted him, and was usually done only two or three times a day. The results left little to be desired. Among the forty cases described in the second paper were sixteen of nasal diphtheria, including very grave ones, in fifteen of which nasal syringing was employed. All of these but one recovered, and the failure in that one was due to exceptional circumstances which have already been referred to. In the much larger number included in the first paper the results were nearly, or quite, as favorable, but cannot be stated so accurately, as the records of all details are less complete.

The writer has in some cases tried the experiment of its more frequent repetition, but the effect was in most so distinctly that of increased prostration and local irritation that it was soon abandoned.

It has been considered necessary by not a few that, in order to secure the efficiency of this procedure, it should be repeated very much oftener—as often by some as every hour. The writer has personally known, in consultation and otherwise, of this having been done in quite a number of cases with successful results, though this has not been invariable. It will, however, be agreed that what can be tolerated by some patients in this disease cannot be endured by all. It will also be agreed that if the lesser frequency of its performance is capable of effecting the object sought, it is preferable to the greater frequency. It will be still further agreed that its effect should in all cases be carefully watched, and that its frequency should never exceed the powers of tolerance of the individual patient.

The choice between enforcing unpleasant and harassing antiseptic measures, on the one hand, and taking the chances of fatal systemic infection on the other, is occasionally in this disease a delicate and perplexing one. The protests that have been made by some in society discussions and medical journals against the former have not been entirely without reason. The fact that some apparently very bad cases of diphtheria do recover without local treatment gives them additional weight. The danger of yielding to sentimental considerations or optimistic security, based on exceptional instances, in the conflict with this insidious disease, is illustrated in the following case: In October, 1880, the writer was called in consultation with Dr. E——, in a mild case of nasal and faucial diphtheria, and was requested to see it with him daily, and direct the treatment. It was the second day of the disease, and there was then no indication of constitutional implication. The child, aged four, was of a highly nervous and sensitive temperament. The family had only lately come under the professional care of Dr. E——, having previously employed homœopathy, and the mother of the child had an especial dread of all harsh and unpleasant therapeutical measures, which feeling the doctor naturally desired should be respected if possible. For this reason a compromise was made with the plain indication for immediate nasal syringing by postponing it, the case to be in the meantime carefully watched, and the urine to be tested twice daily for albumen, Dr. E—— to continue the application, which he was previously making, of carbolized vaseline to the interior of the affected nostril with a camel's-hair pencil. During the two following days the faucial deposit, which was slight and superficial, nearly disappeared, the nasal affection was apparently unchanged, no albumen in the urine, and the general condition of the patient comfortable and encouraging. On the morning of the fourth day the conditions remained about the same. The evening examination of the urine by Dr. E—— was prevented by unfortunate circumstances. During the night feverishness and vomiting set in and continued. On the next day the entire aspect of the case had changed: The urine was scanty and bloody, and loaded with albumen; the symptoms of septic and uræmic poisoning were marked; the nasal affection had become more serious. Nasal syringing was then attempted, but could not be persisted in on account of obstinate and exhausting epis-

taxis. Additional counsel was called in, but the child sank rapidly and died on the sixth day.

Spraying possesses important advantages, and is subject to certain important limitations. Its chief advantages are that it is in itself gentle and unirritating, and not very fatiguing; that by it remedies may be applied in a more direct, evenly diffused, and continuous manner to the oral and pharyngeal surfaces than by other methods, and that they may even, by the assistance of the inspired air, be made to reach the rima glottidis and the vocal cords. It has no valuable applicability to the nasal passages in most cases, and should never be made a substitute in them for syringing. The best instrument for general use is the Delano atomizer, or one of similar construction. Its point should not be thrust far into the mouth, and it should be remembered that even spraying may be done at too short range and too forcibly. Parents and nurses should be trained in its proper performance, as otherwise the spray is quite liable to be wasted on the roof of the mouth or the dorsum of the tongue. To employ it effectually, it is necessary that the mouth of the patient be opened widely. When the procedure is not thus voluntarily facilitated by the patient the writer has found it useless, or worse than useless, to attempt its accomplishment by force. Hence results a most important and unfortunate limitation—that it is not usually available in the cases of children under three years of age.

A great variety of antiphlogistic and antiseptic agents have been applied by this method, such as borax, boric acid, the benzoate of sodium, carbolic acid, listerine, chlorate of potassium, etc. Suitable formulæ for their use, which it is unnecessary to consume time in repeating, abound in text-books and medical journals. The advantages just referred to adapt it especially to the application of mild solvents to diphtheritic membrane.

The slowness of the solvent action of lime-water renders it useless in those emergencies in which rapidity of effect is essential, but does not preclude the possibility of its great utility in a large proportion of cases, in accordance with considerations which have been already presented. Its use was recommended in the two papers previously referred to, in the following combination: ℞. Acidi carbolici, ♏ x.; aquæ calcis, f ℥ iv. M. Sig.: To be sprayed into the throat for some minutes every half hour.

It is worthy of remark that the taste of this combination is very pleasant, but that a very slight increase in the proportion of the carbolic acid makes it less so, and liable to provoke resistance in children. The experience of the writer as to its practical utility may be briefly recapitulated as follows: It has been found to be a very efficient antiphlogistic. It has seemed to accelerate the disintegration and disappearance of superficial membrane, and to assist materially in the antisepsis of the deeper and graver forms. Its utility has not only been observed in faucial diphtheria but it has seemed to have unquestionable efficiency in preventing the extension of the disease into the larynx. In fully one hundred cases in which it was employed in the first series already referred to, it was stated that there was no instance of the subsequent occurrence of serious laryngeal complication, although this was threatened in several by the usual symptoms, and this was also true of the smaller number in the second series, although, as was fully shown, both these groups of cases were of at least the average severity or tendency to severity of true diphtheria as it occurs in this city. A few cases of well-marked laryngeal diphtheria, though of course not of the gravest type, recovered under the early and assiduous use of this remedy alone. The four cases that terminated fatally out of thirty-eight that were treated in the second series—three from laryngeal stenosis and one from toxæmia—were all in children so young that spraying could not be employed. In view of these facts, and their general accordance with the experience of not a few others, it will hardly be thought strange that the writer regards this measure as one of positive therapeutical value, in spite of its mildness and the slowness of its solvent action, and probably in no small degree from those very circumstances.

Of lactic acid and of pepsin it is probably safe to say that, though they have now been for some years before the profession, their practical value as solvents of diphtheritic membrane has not been satisfactorily demonstrated. The digestive solvents—trypsin and papayotin—are at present interesting subjects for experimental study. The former has been recommended in the formula: Trypsin, gr. xv.; sodii bicarb., gr. v.; aquæ, f ℥ ss.; to be applied in spray half-hourly.

The increasing of the solvent power of lime-water by the addition to it of liquor potassæ has been recommended in the treatment of laryngeal diphtheria. While this may be advantageous in cases in which rapidity of action is imperatively demanded, the fact that liquor potassæ, unlike lime-water, is liable, when used continuously, to exert an irritating effect on mucous membranes should limit its employment to such emergencies.

The *inhalation for local effect of vapor* by itself and as a vehicle for various medicinal substances is a well-known and approved resource in the treatment of laryngeal diphtheria. In administering lime by this method it is well to remember that the boiling of lime-water produces a vapor of water and not of lime-water. By the slaking of quicklime, however, a vapor is produced which contains lime. The inhalation of vapors containing turpentine, carbolic acid, oil of eucalyptus, compound tincture of benzoin, etc., is much valued by some as an adjuvant to other remedies.

The *direct application of various substances by means of a soft brush or pencil* may have the special advantages of precision and accurate limitation. It may therefore, in appropriate cases, be made the vehicle of more concentrated or more irritating applications than those which have been previously referred to.

Papayotin has thus been employed by Professor Finkler in combination with salicylic acid, applied about five times in the twenty-four hours; by Dr. Schoffer[1] in a five per cent. solution in water, applied every five or ten minutes; and by Dr. Jacobi[2] in the proportions, papayotin one part, glycerine and water each two to four parts, applied hourly, with results that are encouraging as to its utility.

Bromine in solution thus frequently applied, and also administered internally, constitutes the well-known method of treatment of Dr. William H. Thomson. From a large experience in a military hospital of the special utility of bromine in arresting grangrene the writer would be prepared to expect from it valuable effects in the local treatment of diphtheria, but has not thus employed it.

For escharotic effect upon diphtheritic membrane, nitrate of silver in strong solution has been much employed by some, and has the advantage that its action is superficial, and, with proper limitation, not especially irritating. Carbolic acid and the compound tincture of iodine, either pure or slightly diluted with glycerine, are highly recommended. The tincture of the chloride of iron, in the proportion of two parts to one of glycerine, and Monsell's solution, similarly diluted, have, in a few instances, been applied by the writer to particularly accessible and formidable membranous patches with favorable effect.

It is sometimes objected to the treatment of diphtheria by the methods which have been thus imperfectly sketched, that not only are they in severe and protracted cases wearisome to patients and nurses, but, in order to be effective, require from the busy physician an amount of personal attention which it is often difficult for him to give. The force of this objection must be frankly admitted, and indeed can be appreciated by none so fully as by those who have carried them out in large numbers

[1] Journal of the Society of Chemical Industry, 1885, p. 571.
[2] Therapeutic Gazette, 1886, p. 145.

of cases; but in view of the importance of the issues involved, its validity can be conceded only when it shall be shown that equally good results can be obtained by less arduous measures, which is a therapeutical "consummation devoutly to be wished."

LOCAL TREATMENT OF DIPHTHERIA.

REMARKS ON DR. BILLINGTON'S PAPER BEFORE THE SECTION ON THEORY AND PRACTICE, OF THE NEW YORK ACADEMY OF MEDICINE.[1]

BY A. JACOBI, M.D.,

PRESIDENT OF THE ACADEMY.

MR. CHAIRMAN: The ten-minutes rule precludes my spending more than a second on the expression of my gratification at having been present at the reading of Dr. Billington's paper, and noticing the fidelity with which he adheres to the sound principles laid down by him in a paper read before the Academy in 1876. My gratification is the more intense, as it may be known to some of you that we agree perfectly about most of the general principles in the treatment of diphtheria and their application. As a proof I refer only to my paper on "Diphtheria and Diphtheritic Affections" (*American Med. Times*, August 11 and 18, 1860); "Croup" (*Amer. Jour. of Obst.*, May, 1868); "Diphtheria and Diphtheritic Affections" (*Amer. Jour. Obst.*, February, 1875); "Treatise on Diphtheria," New York, 1880, and my article on "Diphtheria" in "Pepper's Cyclopædia," 1885, and in Gerhardt's "Handb. d. Kinderkrankh.," ii., 1877.

Thus in a discussion on the local treatment of diphtheria I am very much tempted, as you have been so good as to invite me to participate, to extract some of my own writings. As the time is brief, however, I shall content myself with fragments, and add such remarks as I may consider either urgent or new. But, at all events, I do not expect to cover the whole ground, like the lecturer of the evening.

Constitutional diphtheria must be compared with the septic absorption occurring in wounds and in the puerperal condition, and for that reason we are obliged to rely principally on the method of treatment that is most serviceable in cases of surgical wounds and puerperal fever, viz., local disinfection. It can be accomplished by removing, or rather dissolving, the membrane, or by rendering it innocuous, no matter whether it can be readily seen or not. For, after all, the presence of the membrane is the characteristic symptom of the disease, and by absorption the constant source of increasing infection of the system.

Papayotin is easily solved in twenty parts of water. It is certainly a solvent of membrane, and may be injected or brushed over the membrane, or used as a spray. In greater concentration, mixed with water and glycerine (1 : 4–8), I have applied it to the nose, throat, and the trachea, through the cannula, after tracheotomy, with fair results.[2] Trypsin is preferred by others for the same purpose.

The inhalation of steam is very useful in catarrh of the respiratory organs, and also in inflammatory and diphtheritic affections. In fibrinous tracheo-bronchitis it has proved quite successful. But it may prove dangerous by excluding oxygen and overheating the room or tent. Drinking of large quantities of water, with or without alcoholic stimulants, also invites the action of the muciparous glands and aids in macerating membranes. The internal use of ice and its local application can be very useful. But the cases must be selected for each and any of the remedial agents and applications.

In this connection I also refer to a statement of mine made in the *Am. Jour. of Obst.*, February, 1875, viz., that there is a possibility that moist heat, as it "softens healthy tissue as well as morbid exudations, may favor the penetration of the poison into deeper layers." While discussing this remark of mine in his paper read before this Academy on March 16, 1876, on "Diphtheria and its Treatment" ("Trans. Acad.," vol. i., pp. 286 sqq.), Dr. Billington says: "It has also seemed to favor the rapid superficial extension of the diphtheritic disease into the fauces, this having ensued in several of my cases which previously manifested no such tendency."

As steam will increase the secretion from the mucous membrane, and thereby aid in throwing off the membrane, it is advantageous mostly where there are a great many muciparous follicles under a cylindrical or fimbriated epithelium. Where there is pavement epithelium, and but few muciparous follicles—for instance, on the tonsils and on the vocal chords—and the membrane is rather embedded into the tissue than deposited upon it, the steam treatment will do very little good, to say the least.

Mouth and neck must be kept in a healthy condition. Stomatitis, chronic pharyngitis, hypertrophy of the tonsils, glandular enlargements, must be relieved or removed preventively. Acute catarrh of mouth and pharynx requires the use of potassium or sodium chlorate in doses not exceeding a scruple daily for a child a year old, one and a half to two drachms for an adult. The single doses must be small and very frequent, every hour, half or quarter hour. Large doses are dangerous, result in nephritis, and have proved fatal (*Am. Med. Times.*, 1860; Gerhardt, ii., 1877; THE MEDICAL RECORD, March 15, 1879; "Treatise," 1880).

I ought to add here that my explanation of the poisonous effect of chlorate of potassium has not been considered sufficient, methæmoglobinuria being substituted for nephritis. Still, Professor Stockvis, in a recent article containing observations and experiments, returns to my original view and discards methæmoglobinuria in favor of nephritis (*Arch. f. Exper. Path. u. Therap.*, 1886).

The usefulness of lime-water and lactic acid has been greatly over-estimated. Potassium salts have often been recommended, and as often found wanting.

Glycerine is a valuable adjuvant, both externally and internally, but not more.

Turpentine inhalations are deserving of further trials, though naturally they are more effective in purely inflammatory than in diphtheritic processes. I shall return to them later.

Inhalations of ammonium chloride, heated on a stove or burned on live coal, act favorably in catarrhal and inflammatory conditions, and deserve a further trial for the purpose of aiding in the maceration of membranes.

Sodium benzoate does not deserve the eulogies bestowed on it from theoretical reasoning.

Eucalyptus, sulphur, copaiba, and cubebs have been recommended, in preference to other applications, for their effect on catarrhal mucous membranes.

Bromine, both internally and externally, is warmly recommended by William H. Thomson.

Boric acid, in concentrated and mild solutions, has been recommended as a local application to membranous deposits generally, and to the diphtheritic conjunctiva in particular.

I may be permitted to add here that I frequently use saturated solutions—four per cent.—for nasal injections. It is an antiseptic of moderate strength, and very mild, being tolerated as well as a two-thirds of a one per cent. solution of warm salt-water. That property of it is very important. There is no disease in which it is of more vital importance to avoid everything which invites unnecessary resistance and waste of strength on the part of the patient. Not infrequently do I add boracic acid to the solution of corrosive sublimate used for nasal applications in either injection or spray.

Carbolic acid is useful both in local and internal administration according to the end to be reached; it may be used either in concentrated form or in a one per cent.

[1] Read in part only.

[2] Transactions of the Medical Society of the State of New York, 1886.

solution. When it is used for nasal injections care must be taken lest an undue amount be swallowed.

Salicylic acid acts as a caustic when concentrated; in moderate solutions it destroys fetor. Salicylates are antifebriles only.

Deliquescent caustics are dangerous. Injury of the healthy mucous membrane must be avoided. Mineral acids, and particularly carbolic acid, when their application can be limited to the desired locality, are preferable.

Astringents, such as tannin and alum, do not work favorably enough to justify their recommendation in most cases.

Chloride of iron is among the most reliable antiseptic and astringent agents. Small doses in long intervals are quite useless. Moderate doses frequently repeated have a satisfactory general and local effect. A child a year old must take at least four grammes daily; a child of three or four years from eight to fifteen grammes; the same or a larger dose for an adult. The chloride is to be mixed with water and glycerine in various proportions, so that a dose is taken every hour, every half-hour, every ten minutes. Thus other local applications to the throat become mostly superfluous. Potassium or sodium chlorate, from one to four grammes daily, may be added to advantage. This is essentially also the treatment recommended by Dr. Billington in the paper alluded to. It was not necessary on his part, when he referred to my own researches on diphtheria and its treatment, to add that while he coincided with my views in almost every particular, he was not my "follower," except in the order of publications.[1] It is superfluous for me to say that I know him to have arrived at his results independently, and that it was and is a gratification to me to be approved by a painstaking and thinking practitioner and writer.

Among the latest panaceas of diphtheria is, besides internal remedies, a local one in the shape of the galvano-cautery. Dr. Bloebaum, of Coblenz, Germany, has constructed a small galvano-cautery, more or less portable, which is to destroy the first diphtheritic deposit, and thus cure the case. In order to succeed in doing that, it is to be agreed between the patient and his diphtheria that the latter must be within easy reach.

Membranes must not be torn off, and not removed unless they are nearly detached. Caustics are contra-indicated, except where their application can be limited to the diseased surface. No healthy part must be injured. Swelled lymph-glands require ice, iodine, iodoform, mercury, poultices, incision, carbolic acid, according to circumstances, and, at all events, frequent and careful disinfection of the mucous membrane, from which their irritation originates.[2] Diphtheria of the nose is apt to be fatal, unless careful treatment is commenced at once. It consists in persistent disinfection of the nares and pharynx by means of injections. The tendency to sepsis forbids a long intermission of them. They must be continued day and night for one or several days, no matter whether the glandular swelling is considerable or not; for I may here add that there are cases of intense sepsis in which the poison enters the system not by the lymph-ducts, but by the open blood-vessels of the nasal mucous membrane. In these cases there need be no swelling of lymph-bodies.

Some words about nasal injections.

First. A trained nurse, lady-like and conscientious, reported she had made them every hour for five days, and the doctor and herself believed it. I made one, and she admitted she had never succeeded. She never held the syringe horizontally, never succeeded in reaching the other nostril or the pharynx, and nearly killed the child by want of disinfection.

Second. There were two trained nurses, and two children of, I believe, six and four years. When I saw the little four-year-old one, the other was dead. Where did he die? Where? His head between the knees of the trained nurse. They had been told Dr. Jacobi ordered nasal injections to be made every hour in such cases. Every hour the unfortunate boy was lugged out of bed, protesting and fighting, and wearing out his little strength in his battle against two trained brutes; had his head rammed between the knees of one of them comfortably seated on a chair, while the other did the rest; and thus the boy was murdered. When I heard that fearful story from the smiling lips of that person, I begged and pleaded, and showed how to do it gently. The doctor told me a week afterward that the little girl died between the knees of one of the smiling creatures, and neither of them is in the State prison! This is not the proper way of doing it. The whole procedure need not take more than half a minute for the two nostrils; the children may be raised in bed, a towel under their chins. One person holds the hands, the other sits behind and injects *gently*, in order not not to injure the ears. When a child ever complains of the ears, let the liquid be poured in from a spoon. The liquid must be warm, indifferent, such as a two-thirds of a one per cent. solution of salt-water, or as lime-water; or antiseptic, such as a one-quarter to one per cent. solution of carbolic acid, or saturated solutions of boracic acid, or a solution of one part of corrosive sublimate in 2,000 to 10,000 parts of water, with or without 10 to 50 parts of table-salt, or 60 to 300 parts of boracic acid.

When I do not desire to set the children up, I use the same solution as a spray. It can be used while the patients are on their backs or sides. It can be applied often, every hour, every twenty minutes, without harm or annoyance. Only see to it that the nozzle is large and cannot hurt the child. The same must be said of syringes. Formerly I used the hard-rubber ear-syringe, cutting the short end off. Now I use a most simple glass syringe, with vulcanized rubber mounting, which cannot possibly give pain. It is made by the apothecary of Bowery and Second Street.

The question as to the concentration or dilution of antiseptics is a very important one. Knowing that bacteria required rather strong antidotes, I, like others, was at one time of the opinion that bacteria and bacteric poisons could not be interfered with, inasmuch as antiseptics able to destroy bacteria would first destroy blood and tissues. This is fortunately a mistake. It is not the degree of concentration which tells, but the duration of administration or application. A permanent irrigation of a three per cent. solution of carbolic acid is dangerous; the desired effect can be obtained by a much weaker preparation when used frequently or constantly. In one of his careful and suggestive papers on the effect of carbolic acid on vibrating cells and leucocytes, in the *American Journal of the Medical Sciences* for January, 1881, Dr. T. Mitchell Prudden proves that a solution of one-sixteenth of one per cent. of carbolic acid prevents the emigration of white blood-corpuscles under circumstances otherwise favorable to inflammation; and another careful investigator, Koch, finds that though bacteria are not easily killed, their growth is stopped by a solution of 1 part of carbolic acid in 850, and their activity by one of 1 part in 1,200. This is all that is required in the large majority of the very worst cases; and these experimental discoveries bear out my clinical experience of the usefulness of great dilutions of carbolic acid. In regard to injections and spray, I again insist upon their frequent repetition, and have also combined with them, for years, another practice, which consists in permanent inhalation of turpentine or carbolic acid, or both. In the room of the patient water is kept boiling constantly, not on gas, if possible, because of the large amount of oxygen which it consumes; not over alcohol, if I can help it, but over the fireplace, provided the steam is prevented from escaping directly into the chimney. Every hour a tablespoonful of turpentine—preferably the crude—and

[1] Loc. cit., p. 291.

[2] Swelling of the lymph-bodies near the angle of the lower jaw means diphtheria of the posterior nares.

a teaspoonful or more of carbolic acid is poured into the boiling water, and the air of the room filled with the vapor.

Inunctions of iodide of potassium or mercury cannot be looked upon as local treatment under ordinary circumstances, for their effect is a general one. When Dr. J. L. Smith (*American Journal of the Medical Sciences*, April, 1885, p. 335) quoted me as having advised the inunction of mercurial ointment into the region of the larynx, in membranous croup, he mistook my meaning. Still, I can imagine that if iodide of potassium, or mercury, or another absorbent, could be readily and speedily introduced into the fearful adenitic and periadenitic swellings round the neck, they might be found useful. Thus far there has been no possibility of accomplishing that much until lately, for the common officinal ointments are just as many placebos, and their use acts simply as a gentle massage. Oleic acid, it is true, will penetrate the cutis easily, and carry medicines with it, but it irritates. Pure lanolin acts very much better. Years ago I found iodine in the urine three hours after the application of an ointment prepared by dissolving 1 part of iodide of potassium in water, and mixing with 2 parts of lard and 6 parts of *pure* lanolin. It has thus been traced within an hour. A syphilitic tumor of the mediastinum I have seen diminished by iodide of potassium inunctions, in lanolin, without using anything else. Thus I should recommend in future to try hydrargyrum or iodoform lanolin ointments in such septic swellings. I can also imagine that the injections of iodoform dissolved in ether will have a good effect in destroying some of the deposited poison and preventing its spreading, and I shall try them.

The local treatment of laryngeal diphtheria consists of emetics, such as zinc, copper, or turpeth mineral, when half-detached membranes are to be removed, and in tracheotomy. Let me add here at once, *in intubation*, thanks to the most modest and most deserving of all men, Dr. O'Dwyer.

The local treatment of diphtheritic paralysis requires friction, hot bathing, the faradic and galvanic currents, and sometimes the hypodermatic administration of strychnia.

Diphtheritic conjunctivitis is benefited by ice-cloths repeated every few minutes, and boric acid; cutaneous diphtheria, by local cauterization and disinfection. The application of iodoform in powder, or a ten per cent. iodoform vaseline ointment, or carbolic acid concentrated, or in glycerine or alcohol solutions, of from five to fifteen per cent., repeated frequently or less so, will often prevent the poison from spreading into the neighboring lymph-bodies and the blood.

Retention of Placenta for Twenty-two Months.—Dr. Rangé reports in the *Journal des Layes-Femmes*, January 1, 1887, the following case: A woman, thirty years of age, primipara, had a miscarriage in September, 1879, at the second or third month of pregnancy, followed by severe and repeated hemorrhages. No doctor was called in, and little is therefore known of the circumstances or causes of the accident. The hemorrhage continued for some time, gradually getting less, and ceased entirely for four months, reappearing in April, 1880. Since that date the patient suffered constantly from severe abdominal pains, with red and white discharges, and a deranged state of the bowels. Matters mended to some extent, and the patient thought she was getting well again when, in July, 1881, she was seized with labor-pains, and in two hours was delivered of a placenta in a state of putrefaction, about the size of the closed fist. She made a tedious but perfect recovery. This patient had had no marital intercourse since her miscarriage, and no doubt is therefore possible as to the reality of the placental retention having lasted twenty-two months.

ON THE SURGICAL TREATMENT OF BRAIN SUPPURATION FOLLOWING EAR DISEASE.[1]

By ROBERT F. WEIR, M.D.,

SURGEON TO THE NEW YORK HOSPITAL, AND PROFESSOR OF CLINICAL SURGERY, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

It not infrequently happens, during the progress of a mastoid disease, and even when the latter has been relieved by properly performed operation, that a series of symptoms develop themselves which carry despair to the heart of the aural surgeon. I refer to the brain complications which, while possible with an intact membrana tympani, are commonly associated with long-continued purulent discharges from the middle ear, with generally a mastoid involvement. In Schwartze's collection of one hundred cases of mastoid perforations there were twenty per cent. of deaths, and in only one could the fatal result be attributed to the operation. Other aurists have had a mortality nearly similar. It was my fortune to witness death occur in five cases with cerebral symptoms during my eight years' connection as aural surgeon with the New York Eye and Ear Infirmary, but with the less frequent opportunities of studying the complications that have come to me in late years, I have only once been able to make an uncertain step forward to rescue a patient doomed in this manner to destruction.

This was in 1884 when, on December 19th, a woman, thirty-nine years of age, was admitted to my ward in the New York Hospital, who gave the history that seven weeks before she had injured her right thumb, which had become painful and swollen. While the inflammation was in progress, severe headache came on, associated with a discharge from the right ear, which, however, continued but a short time, though it was followed by deafness on that side. Two weeks prior to her coming under my charge she had had the thumb incised and a quantity of pus let out. Her headaches, however, continued, and she had fever and chills, loss of appetite, and vomiting. One week after the incision was made in the thumb she complained of leg-pains, and had difficulty in walking. On admission, she was found with a temperature of 101½°; respiration, 16; pulse, 64; but no paralysis was detected on ordinary examination, though she was heavy and inclined to be stupid and lethargic.

The finger was healed, and no inflammatory action existed along the forearm, arm, or in the axilla. There was, however, œdema and tenderness over the right mastoid region, and pain was complained of over the whole right side of the head, and some was also felt along the right side of the upper spine. The membrana tympani of that side was perforated largely, and the ossicles were plainly visible. Though covered by swollen mucous membrane, no discharge was seen, and no puffing or swelling of the face existed. Urine was free from albumen and sugar.

As the indications were plain for opening the mastoid a section of the soft parts was made and the bone exposed and perforated, at first with a drill and afterward with a chisel, following the directions of Schwartze, Buck, and Hartmann, until the antrum was reached, and a small quantity of pus evacuated. The antiseptic fluid (sublimate solution, 1 to 2,000) could not, however, be syringed from the mastoid into the ear. The wound in the bone was packed loosely with iodoform gauze and an antiseptic dressing applied. As a result of this operation the temperature fell to 99° and the pulse rose to 82, and her hearing decidedly improved on that side, but she still complained greatly of general headache. This symptom persisted with increasing violence, and eight days later the pulse sank to 58, and the right eye showed, by ophthalmoscopic examination by Dr. Andrews, a choked disk. In view of her deteriorating condition, I determined to

[1] Read at the discussion on Mastoid Disease, at a meeting of the Section on Ophthalmology and Otology, New York Academy of Medicine, held March 21, 1887. Since the reading of this paper the British Medical Journal for March 19th has come to hand, and in it is a synopsis of two cases by Mr. Miller, where a low down opening of the temporal bone had relieved a cerebral abscess, but with a subsequent fatal issue from pyæmia.

practise in her hopeless condition what I then felt to be a rather heroic remedy, viz., to open the skull and try by probing the brain to find the abscess which I supposed was there. I therefore, under ether, on March 29th, enlarged with gouge and rongeur forceps the original mastoid opening upward and forward for half an inch, and deepened it until the dura mater was exposed nearly the size of my finger-nail. Cutting through the membrane I introduced several times a hypodermic needle to a depth of nearly an inch and a half, directing it along the upper part of the petrous bone and also into the cerebral lobe in this region, but nothing but a little blood was extracted. The wound was again packed with iodoform gauze and dressed as before. No good nor any harm resulted from this exploratory operation. Three days later she apparently improved, coincident with an increased discharge from the wound; this amelioration, however, was but temporary. Eleven days after this last operation she became hemiplegic on the *right* or same side as the ear trouble, with a temperature of 103°, and pulse 68, and irregular, with vomiting. Under these discouraging circumstances a further ineffectual attempt was made to relieve her. With a one-inch trephine a button of bone was removed over the left Rolanderic line, and the dura mater incised crucially, and quite a large quantity of nearly clear cerebro-spinal fluid, approximated at two ounces, let out. Six exploratory punctures were then made with an aspirator, but nothing was detected. The patient was not bettered and died the next day, comatose. An autopsy was refused.

This case led me naturally to a further consideration of the subject and to repeated dissections, and I had, with the recent experience gained from an unsuccessful attempt at removing a sarcoma from the brain,[1] arrived at the conclusion (and was helped in this by the advice of my friend, Dr. Seguin) that a bolder explorative operation and search for a brain abscess was permissible, and I waited only another opportunity to put into practice my surgical convictions on the point when the brilliant results of Horsley[2] in the removal of cerebral tumors, and of epileptogenous brain-tissue, a procedure inaugurated by Bennett and Godlee in 1884, taught the surgical world the comparative innocuousness of largely planned openings of the cranium, and the tolerance of the brain itself to manipulative interference. Later than this, and more germane to the topic of the evening, are the results, known doubtless to you all, obtained by Barker,[3] of London, who published with Dr. Gowers, in December last, the happy result of daring brain surgery obtained by trephining for a cerebral abscess following mastoid disease. This latter bone had been early opened, relieved of the purulent collection, and washed out with antiseptic lotions through the auditory canal. Seven days later, rigors persisting, and the patient's lethargy and vomiting continuing with intense optic neuritis, Dr. Gowers was led to the conviction of the existence of a brain abscess, and asked Mr. Barker to relieve the patient, which was effected by opening the cranium. The temporo-sphenoidal fissure was exposed as a landmark, when an aspirator needle, thrust inward, forward, and downward, *i.e.*, toward the petrous portion of the temporal bone, gave evidence of pus. This track was enlarged, and nearly one ounce of matter was evacuated and drainage accomplished by a rubber tube. Two weeks after the operation the tube was removed and the patient allowed to get out of bed. Complete recovery took place.

Immediately following this interesting case was another, published in the *British Medical Journal* for February 12, 1887, by Dr. Greenfield,[4] and operated on by Mr. Caird. The cerebral symptoms had existed for eleven weeks, and followed a suppurative inflammation of the left ear; the mastoid, however, was not involved. The signs of pressure were more marked than in the preceding case. There were present ptosis of the left eye and dilatation of the same pupil, but no paralysis of the limbs, tongue, or face. The left optic papilla was greatly swollen, cloudy, and gray, with blurred edges. The right was slightly ill-defined at the apparent lower margin, but elsewhere was clear. These symptoms led Dr. Greenfield to believe that the abscess was in the temporo-sphenoidal lobe, and that it extended forward and inward, so as to occupy a position near the front and toward the inner aspect of the lobe. The trephine was placed one inch above the zygoma, and one and one-fourth inch behind the external angular process, and on removing the button of bone the dura mater bulged forward and was pulseless. On reflecting the membrane, and plunging a Graefe's knife half an inch inward, matter was struck, and about two ounces of pus thus escaped. Subsequently it was found that fluids injected in the ear came out through the wound. The patient fully recovered within a month. Another successful case has just been reported by Macewen, of Glasgow,[1] but no details have been published.

It was at first thought that English surgery was to be credited with this marked advance, but early in 1886 a case was reported by Truckenbrod[2] which had been successfully operated on by Schede, of Hamburg. His case was one of left-sided chronic purulent ear disease in which febrile symptoms, pain in the head, and chills developing, the mastoid was opened with evacuation of pus and temporary improvement of the patient, but on recurrence of his symptoms, with augmentation of nerve symptoms, such as paresis, aphasia, and right facial paralysis, the diagnosis of brain abscess was arrived at, and the skin opening of the mastoid was enlarged upward, when a tiny bone fistula, discharging pus, was found just above and behind the external auditory canal. This was enlarged until the dura was exposed, when more pus escaped, but insufficient to account for the symptoms. Exploratory puncture through the dura not detecting the site of the abscess, the thin layer of the temporal bone was chiselled through five centimetres downward and backward, the dura mater then split, and an abscess of the size of a small orange revealed and evacuated. Its cavity was washed out with 1 to 1,000 sublimate solution and drained. Immediate relief followed, but twice during the progress toward recovery it became necessary to puncture and drain the abscess-cavity anew. In eighteen weeks the patient was discharged. Some interesting nerve conditions followed the recovery, but do not concern the present question.

This case of Schede's, while perhaps more correctly surgical, as will shortly be further shown, is hardly to be classed in brilliancy with the operation of Barker and Caird in respect to the correct previous localization of the purulent depôt, and is more closely allied to one reported by Ogston,[3] who in 1876 trephined the skull for a cerebral abscess following middle-ear disease with caries of the mastoid and the adjacent parietal bone. By this operation nine ounces of pus were evacuated from between the dura mater and the diseased bone. The brain was not opened. A communication existed between the abscess and the auditory canal. Recovery was perfect, save the atrophy of the optic nerve, and the permanently dilated pupil on the side of the ear and abscess trouble.

A nearer approach to the ideal operation, as far as technique is concerned, is the one briefly sketched at a recent meeting of the Medical Society of London by Mr. James Black,[4] who, in a patient with cerebral symptoms from aural disease, after failure had resulted from drilling the mastoid, trephined the skull an inch and a quarter above and behind the external auditory meatus, and explored the brain for the abscess. A second exploration

was subsequently made through the same opening with a trocar and cannula, but no pus was found. In spite of severe constitutional symptoms, the wound healed well, with the exception of a small sinus, and the patient ultimately made a good recovery. Schondorff's case,[1] which is quoted by Greenfield, had less interest in it. It was as follows: A man had acute purulent inflammation of the middle ear, which was accompanied by mastoid inflammation, abscess, and fistulous discharge. A year later, brain symptoms showed themselves, the mastoid was opened, and some pus found. The next day a fistula was detected in the bone cavity, and enlarged, when about sixty grammes of pus was let out. This fistulous bony track was subsequently cut open, and found to run across the lateral sinus, which was thus exposed nearly to the median line posteriorly, and was thought to be due to phlebitis. The patient recovered, no incision being made into the abscess, it only being drained and washed out through the enlarged bony fistula.

A short research through the authorities on aural surgery will show that the intra-cranial complications occurring with septic inflammations of the ear, whether bony or otherwise, are purulent meningitis, cerebral abscess, phlebitic thrombosis, and pyæmia, the two former being the more common, and the least readily recognized. It is not my intention to go into the subject of the diagnosis of these affections, and particularly that of cerebral abscess. It is well known that the regions in which such purulent collections are most commonly found are those which afford the fewest and most unreliable symptoms for localization. Hence, my endeavor has been rather to direct attention to certain facts, not hitherto clearly made known, that may contribute clinically a little more certainty to a previous hesitating treatment. A somewhat cursory examination of a series of cases of cerebral abscess, from the time of Meyer's monograph on this subject to the present period, has shown me, not only that nearly one-fourth[2] of all such abscesses are of ear origin, but, what is of more importance, that out of 44 cases,[3] in which only two double abscesses were met with, 24 were found in the temporo-sphenoidal lobe, 15 cases in the cerebellum, 2 in the frontal lobe, 1 in the posterior cerebral lobe, 1 in the pons, and 1 in the corpora quadrigemina. This hardly corroborates the statement made in the recently received brief report of the discussion on cerebral abscess in Glasgow, by Mr. Barker, that cerebral abscesses were three times more frequent than cerebellar ones. The situation of an abscess also depends, to some extent, and probably more so than we can always appreciate, upon the route by which the inflammation extends from the ear-passages, the line of extension being usually along the anastomosing veins and lymphatics, or nerves,[4] and more often from continuity from existing bone disease, or from a thin or non-present tegmen, or in children chiefly through the incomplete petro-squamal suture; the condition of long-tarrying pus, however, being by far the most important of all the factors in the self-infection. I found in my collection of 44 cases that the 24 abscesses of the temporo-sphenoidal lobe were associated with caries on the anterior wall of the petrous bone fourteen times, with mastoid caries six times, and with anterior phlebitis once. Its situation was not stated in the three remaining autopsies. In the 15 cerebellar abscesses, it was noted that the infection progressed from caries of the posterior petrosal surface six times, from internal ear caries three times, from mastoid disease twice, and by means of the aqueduct veins once, by the facial nerve twice, and once it was not stated. This sustains measurably Gull's modification of Toynbee's law as to the influence of the locality of the lesion. The important surgical fact, however, comes out strongly, that a majority of the purulent depôts in the brain from ear disease are encountered in the temporo-sphenoidal lobe, and that after this the most affected locality is the cerebellum. It should be as decidedly kept in mind that both the regions involved are fortunately of less value to life, and can better permit surgical interference than almost any other portion of the brain. It is to the fact of their slight motor importance that our power of localizing tumors and abscesses in these regions is so poor, and this consideration leads directly to the remark that the earliest decided evidences of brain-pressure in the diseases under question should be acted upon as soon as detected, since their development presupposes an already large accumulation of pus. It is for this reason, therefore, that I would advocate surgical interference with the brain as soon as a mastoid operation has shown us that the symptoms have not been satisfactorily relieved by this operation. Recall here, in this connection, the statement that one-fifth of the cases of cerebral abscess die unrelieved by the mastoid operation, and its weight will be felt. There is a peculiarity which others beside myself have observed: it is, that after both a successful and unsuccessful mastoid perforation (*i.e.*, as regards reaching pus) there is often a decided improvement in the symptoms, followed after a day or two by a progressive deterioration; and, further, it has been occasionally noticed that through the mastoid opening an amount of pus has been discharged far beyond what the cells could contain, and this in several instances has continued for a day or two. Taking such conditions, and those that have been given, with Ogston's, Schede's, and Schondorff's cases, it is a fair inference that either the cerebral abscess itself has been relieved by the mastoid operation, or, what is more likely, that an extra-dural collection of matter has been drained by the mastoid opening. I cannot but help thinking, when considering these instances, that even in this direction surgery can do more than it has hitherto done, and that by a cranial operation the dura could easily and safely be lifted up to a point corresponding to the roof of the tympanic cavity. This I have done experimentally on the cadaver without difficulty. In truth—and I hesitate lest the charge of rashness be thrown at me—I cannot see, anatomically or surgically, any adverse reasons, in a suppurative meningitis of the middle fossa, of aural origin, why an early outlet should not be provided for its infectious products by opening the dura and draining the fossa. Reflection will show a surgical analogy to plainly exist between the petrous bone and the appendix vermiformis. As in the latter, one may have a general peritonitis or a localized abscess bounded by matted intestines, or one may have, better yet, a connective-tissue abscess, all depending mainly on the rapidity of the ulcerating process; so in the petrous bone, from reasons more varied, perhaps, than in the appendix, one can expect, first, an extra-dural inflammation, which, according to my idea, can and should be relieved, or an attempt made to do so; second, an acute suppurative meningitis, due to the direct perforation of the dura or to the infection along vessel-channels; and third, the cerebral or cerebellar abscess, often of pial origin and beginning in a deep convolution, and secondarily involving the cerebral substance. This may be fanciful to some, but it will serve, perhaps, to impress the point of my remarks more deeply.

The outcome of all these observations is in the advice that, in the case of ear disease presenting cerebral symptoms, without definite possible localization, the mastoid cells should be opened at the point where it curves into the meatus (according to Dr. Buck's suggestion). If pus is discovered and satisfactorily evacuated, delay can be resorted to, in the hope that this relief may be sufficient. If it is shown that the improvement is nil, or only temporary,[1] the procedure of Schede accords most with my

[1] Arch. f. klin. Chirurg., Bd. xxxi., S. 316, 1885.

[2] Barker says (Br. Med. Jour., February 19, 1887) more than thirty per cent. of the cases of cerebral abscess are due to ear disease. He also states that cerebral abscesses are three times more frequent than cerebellar abscesses.

[3] Which I have obtained from the records of Archiv. f. Ohrenheilkunde, vols. 1 to 23.

[4] To the cerebellum along the seventh nerve, as has been reported by Rotholz and Hartmann, Archives Otology, Bd. xv., 559.

[1] And keeping in mind that the duration of cerebral abscesses is not always long, as it has been shown by Meyer that in 34 cases 13 died in one week, 7 in two weeks, 4 in three weeks, 8 in five weeks, and the other 2 within nine weeks.

own views, viz., to enlarge the mastoid opening upward and inward until the dura is exposed over a space of half an inch, when, if no oozing of pus shows an extra-dural abscess, the test-point of the exploration is to be made by carrying a director, or the flat end of a rather large probe, along the anterior surface of the petrous bone for a distance of nearly two inches, which will be not more than an inch and a quarter beyond the inner surface of the skull. Trials on the cadaver show this to be easily effected, and no reason leads me to believe it to be hazardous in the living patient;[1] and its importance will be appreciated in recalling that two-thirds of all the temporo-sphenoidal cerebral abscesses are associated with recognizable disease of this portion of the bone.[2] Should such a carious spot be thus detected, the exploration itself may possibly bring about the immediate emptying of the cerebral abscess, or, if it does not, it renders more certain the next procedure, which is to open up the region above the external auditory canal by a trephine of good size, the centre of which should be applied about an inch and a half above this landmark, or the exploratory opening of the skull can be enlarged upward by a chisel or double-gouge forceps, until a decidedly large opening is made. A large opening, I may remark, not only adds nothing to the risk of the operation, but also allows the ready control of the possible hemorrhage from the middle meningeal artery, here quite large, and which can be easily caught up by a forceps, or tied after division of the dura, or if channelled in the bone can be plugged with a sharpened match or by crushing the diploë with the jaws of a forceps. The bulging of the dura mater into the skull opening, and the absence of its usual pulsation, will be strong evidences of the correctness of the diagnosis. The use of a hypodermic needle can be now resorted to, if wished, without opening the dura, though the examination of the brain is rendered more satisfactory, by its changes in color, etc., by turning a flap[3] of this membrane upward (which direction is better on account of the possibility of the use of a drainage-tube, and should, therefore, be borne in mind and acted upon, except in those cases when in the vicinity of a sinus, such as the lateral, when the attached base of the dural flap should always be toward the venous trunk). For such explorations I prefer, and have used, rather large and long hypodermic needles, blunted at their ends, by which vessel-injury is avoided. They should be carried at first certainly toward the petrous bone, then forward, and subsequently backward. Should an abscess of large size be encountered, and in which the lowness of the cranial opening here advised should not answer for thorough drainage, as, however, it is believed it will, better than with a higher opening, the question of a second cranial counter-opening should be taken into serious consideration, particularly if no motor-tract would be involved in accomplishing the same. The need of such a counter-opening was amply demonstrated by Dr. H. D. Noyes in his case of a gravitating cerebral abscess, and it has been corroborated in my own hospital service, and its good effects shown in similar recent cases by Fluhrer, Powers, and others.

When symptoms are present by which the probable site of the purulent collection can be located, whether in the temporo-sphenoidal lobe or in the cerebellum, the surgeon will be guarded largely by the neurologist. In Barker's case, with such help, the skull opening was made an inch and a quarter behind the centre of the cartilaginous meatus of the ear, on a line perpendicular to Reid's base-line, which is a line running from the inferior border of the orbit through the auditory opening.

If symptoms should point toward a cerebellar abscess, by the absence of auditory bone conduction or by titubation or other distinctive symptoms, or should, in an extreme case, and warranted by the necessary mortality of the disease, a cerebral abscess be excluded, a further exploration beneath the tentorium be decided on, I can state, with some positiveness, that the cerebellar region is not inaccessible to surgical attack. I have at this time no experience of my own, or even of others, to bring on this subject save that attained in the dead-house. But quite a number of rehearsals have shown me that the cerebellum can be readily reached by cutting an oval flap of the scalp from above downward, and separating the muscles from the superior curved line of the occipital bone—in doing which probably the occipital artery and nerve will be wounded, and the former require to be cared for by ligature. The skull in this region is quite thin, and after exposure can be easily opened and the dural flap turned upward so as to keep its base toward the lateral sinus,[1] the lower edge of which is clearly defined externally, if encroached upon, as a transverse cord-like line. With a moderate exposure accomplished in this way, and with the use of spatula to lift it up slightly, the cerebellum can, if necessary, be viewed, with an electric light, nearly to the foramen magnum.

A guide in operating on the cerebellum has been suggested by Mr. Barker, which is that, before proceeding to open the skull, the mastoid wound of the soft parts should be carried back far enough to see the opening of the mastoid vein, as he believed that if inflammation existed in the posterior aspect of the petrous bone it could hardly reach the cerebellum without forming a layer of pus under the dura mater of the lateral sinus. If this is so, pus will escape by the mastoid foramen, if the latter be exposed. This point should therefore be kept in mind.

Let me say, in concluding, that the great gravity of the affection to which I have so imperfectly asked your attention has justified me, I hope, not only in occupying so much of the time of the Section, but also in presenting to your thoughtful consideration procedures which, while bold and novel in sound, are based upon the rapid but real development of scientific brain-surgery.

THE GONOCOCCUS IN GONORRHŒAL ARTHRITIS.—Dr. P. V. Smirnoff has examined the sero-purulent fluid aspirated from the inflamed knee-joint of a patient, aged twenty-eight, in whom arthritis had developed about a month after his contracting gonorrhœa. Numerous groups of Neisser's microbes were found within the pus-cells. Hence the author comes to the same conclusion as Petrone, Kemmerer, and M. I. Afanasieff—that is, that the articular inflammation is caused by the gonococci entering the blood

---

[1] The above conclusions have been confirmed in the Lancet of March 12th, and the Brit. Med. Jour. of March 19th, received since the reading of the paper, by the report of Dr. McBride and Mr. Miller of two cases of cerebral abscess relieved in an almost precisely similar manner, the patients, however, succumbing from pyæmia. In the Lancet for March 26th will be found the details of Macewen's successful case of cerebral abscess alluded to in the text. The opportunity of proof-correcting fortunately enables me to further complete this subject.

[2] Barker, in the brief synopsis of his paper at the Glasgow Medico-Chirurgical Society (Brit. Med. Journal, February 19, 1887), says that nine-tenths of the tempero-sphenoidal abscesses lay within a circle three-fourths of an inch in diameter, the centre of which was an inch and a half behind, and the same above, the centre of the meatus.

[3] The resort to a flap instead of an ordinary plain or crucial incision is to meet the contingency of failure to detect an abscess. If such is recognized, the base can be split or the flap removed, as wished, to permit the necessary drainage.

[1] Too much stress is, I think, laid on wounds of the longitudinal and lateral sinus. I have in four instances met with a wound of the longitudinal sinus with fracture, and once a similar wound of the lateral sinus. In all, the hemorrhage was promptly controlled by a tampon, without detriment to the patient. I have wounded the lateral sinus in a mastoid operation, and, without any difficulty, checked the hemorrhage, and the patient recovered. The sinus in the living are much broader than is supposed—the longitudinal is often one inch broad, and similarly the lateral. This can be proved by injecting them in the cadaver. I have, in two cases, removed the bone over the longitudinal sinus without causing any marked hemorrhage, and have exposed the whole width of the lateral sinus in a mastoid operation without any bleeding or evil results. Schondorff, Lucal, and Knapp have had a similar experience. More good could be accomplished in caries of the petrous bone were aural surgeons not rendered unduly timid by fear of damage to the sinus, which is, however, generally out of their field of operation, and also from their dread of exposing the dura mater. In the many instances where a fistulous track, leading to carious bone, exists through the mastoid, which is difficult to follow, the injection of the same with some innocuous staining fluid, such as iodine or one of the aniline dyes, might enable a surgeon, with a wide external opening, and the use of fine scoops, etc., to clear out the carious patch, and to open squarely into the tympanum, as effectually as is now done elsewhere in bone abscesses contiguous to joints. The color of the dura mater is sufficiently pronounced to give warning against proceeding farther in any given direction, when it presents itself.

A NOVEL SYSTEM OF OPERATING FOR THE CORRECTION OF THE DEFLECTED SEPTUM BY MEANS OF AN ELECTRIC MOTOR, NASAL DRILLS, AND AN ORIGINAL SPRAY-PRODUCING DEVICE, WITH ILLUSTRATIVE CASES.[1]

By WILLIAM CHAPMAN JARVIS, M.D.,

PROFESSOR OF LARYNGOLOGY AND DISEASES OF THE NOSE AND THROAT IN THE NEW YORK UNIVERSITY MEDICAL COLLEGE, CONSULTING LARYNGOLOGIST TO THE OUTDOOR DEPARTMENT OF BELLEVUE HOSPITAL.

Despite the numerous methods which have been advanced by laryngologists for the correction of malformed or displaced septa, no single procedure or device has evidently been invented which can justly claim the right of universal applicability for the successful treatment of the conditions met with in this deformity. Rather than view this as an indication of inefficiency or irresolution, I would, on the contrary, profiting from the common experience of the past, interpret the formidable array of instruments as a commendable effort to successfully cope with the various contingencies which may be met with in the treatment of the deflected septum. It is even difficult to imagine a single instrument possessing the combined property of cutting with facility and precision the hardest bone or softest membrane. This, nevertheless, would be required of an instrument designed for the successful treatment of deflected septa, composed, as they may be, of hypertrophied mucous membrane, dense, elastic cartilage, or compact bone.

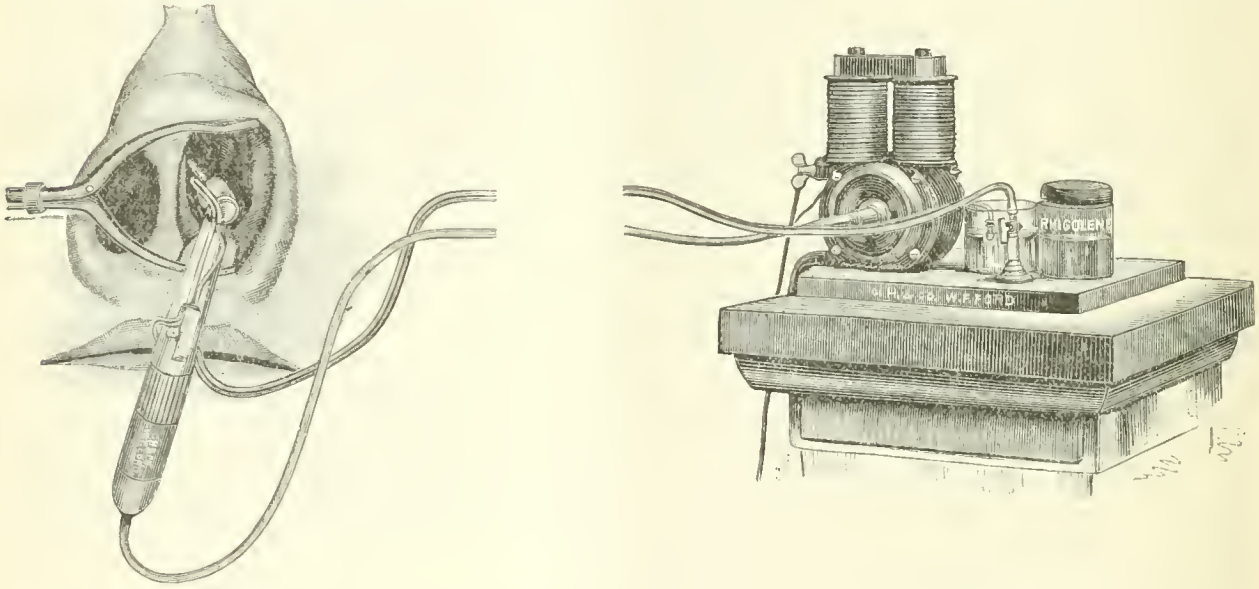

Fig. 1.

Several devices have been already brought forward by me for curing the deflected septum, which, judging from their liberal acceptance in print and practice, have more than survived the usual surprise provoked by the presentation of therapeutic novelties. I do not desire this addition to my septum armamentarium, namely, the electric motor and novel system of drilling, to be interpreted as an expression of dissatisfaction with earlier procedures, but rather as an intention to make these operations more effective. Indeed, I rarely if ever complete an operation upon the septum by means of the electric drill alone, for the reason that my delicate punches, cartilage-scissors, and bone-forceps afford valuable assistance for the removal of adherent tissue débris, in the form of shreds of mucous membrane or cartilaginous and osseous asperities.

A sufficient experience with the common treadle surgical engine, and particularly with an improved form of this apparatus, invented and used by me during an extended period for intra-nasal operations, has convinced me that the natural dread occasioned by the sight of the cumbersome and rapidly revolving noisy machinery constitutes a menace to the usefulness of the nasal drill. This sometimes serious objection, though mostly of a psychical nature, is effectively overcome by the employment of the electric motor, concealed in its narrow shell suspended in mid-air, but few patients possessing an idea of the great power conveyed by the quiet, mysterious movements of this apparently insignificant mechanism.

My earliest results with the electric motor, in operations upon the septum, were obtained by means of a very ingenious dental instrument, devised by the late Dr. Robert Arthur, of Baltimore, and for the use of which I am indebted to my friend Dr. George Arthur, U. S. N. This little instrument, used by me not quite two years ago, was constructed to combine the greatest amount of working power with the smallest bulk, inasmuch as the drills and magnet were held in the hand, after the manner of a pen-handle, the mandril and drill-chuck being a direct extension of the armature. The efficiency of this motor is dependent upon the great number of its revolutions, that is, the acquired momentum, and it satisfactorily serves the purpose for which it was intended, namely, drilling the teeth. Although I succeeded in cutting away the dense structures entering into the formation of extensive deviations of the septum, the frequent retardation of the drill's revolutions when unusual pressure was exercised, gave rise to inconvenient delay in acquiring fresh momentum. For this reason I was compelled to abandon the employment of Arthur's hand-motor and turn to bulky but more powerful devices of the kind to accomplish my purpose. I nevertheless believe that the application of direct power, in accordance with the principle of Arthur's motor or Robert's electric osteotome, is the most rational, inasmuch as the loss of power through friction is reduced to a minimum.

The weight of electric motors possessing great rotatory inertia renders the employment of a cable and independent hand-piece necessary. The first motor of this pattern, seen by me several years ago, was one known as the Hussey motor. Being intended for dental purposes, it was operated by means of a flexible cable, the weight of the instrument being supported by a cord attached to the ceiling. I experimented with one of Hussey's larger motors, but was disappointed in the instrument. Dr. Seiler drew my attention to the Griscom motor several years ago, and I embraced an opportunity to study its action for an extended period, but was not perfectly sat-

[1] Presented at the New York Academy of Medicine (Laryngological Section), March 23, 1887.

isfied with the instrument. To Dr. Carl Seiler, I believe, is due the credit of first calling the attention of the medical profession to the utility of the electric motor in intranasal surgery.

The experience just described led me to discover and utilize the powerful but compact C and C electric motor. Inasmuch as this instrument has proved in my hands the desideratum sought for, I shall give it exclusive attention, only referring to other motors for purposes of comparison. This electric motor is shown in Fig. 1, together with the accessory operating appliances. The axle-shaft can be discerned projecting from the centre of the motor-box. By simply unscrewing the face-plate the component parts of the motor can be readily reached and examined. The armature, of the ring type, is wound continuously, wire of trapezoidal section being used. The commutator brushes are so arranged that no injury can arise from reversing the motion of the armature. The commutator segments, seventeen in number, are placed in a circular manner, being separated by an interval of only one-sixteenth of an inch. This close arrangement of the segments secures uninterrupted and great power without sacrificing speed. Hence there is absolutely no dead-point, a prevalent objection with electric motors, and the common annoyance of laboriously adjusting the armature at intervals during an operation is, by this device, relegated to the inconveniences of the past.

The counter-electromotive force generated by the motor running at 1,800 turns a minute, with an 18-ampère current in the field, is 5 volts. The revolutions can be carried as high as 2,000 to the minute. Its extreme capacity equals $\frac{1}{8}$-horse power. The dimensions of the instrument are $7\frac{1}{2} \times 5 \times 3$ inches, and weight 12 pounds.

A single quantity-cell supplies sufficient electromotive force for any ordinary nasal operation; two of these cells furnish an excess of power, even in operations including the densest portion of the vomer. To facilitate the attachment of the flexible shaft, I have had constructed a metallic sleeve which slips over the journal-box of the motor. Within this sleeve is an angular rod, soldered to the flexible cable, which slips in a groove cut into the centre of the axle of the armature. The free movement of this rod within the groove favors the flexion of the cable, and permits the shafting to be quickly attached or withdrawn. The electric motor can be used either attached to a convenient table or suspended by wires from the ceiling.

The wires running from the battery are interrupted before reaching the motor and arranged upon a foot-board. The convenient cut-off thus formed is simply composed of a sheet of spring brass, which the pressure of the operator's foot brings in contact with a button, through which the electric current is conducted to the motor. This device, I have been recently informed, has been likewise invented by Mr. Griscom. Although it is possible by this arrangement to instantly cut off the current, if desired, the sudden interruption of the electric flow is not really required, inasmuch as the easy withdrawal of the small nasal drills, even while running at full speed, is a very simple procedure.

After experimenting with several kinds of batteries, I have finally settled upon a modification of Bunsen's cells, a plunge and a gravity battery, as the most convenient.

My improved plunge battery is so arranged that a succession of cells can be automatically thrown into the circuit by simply raising the lid of the box which supports the elements, sliding it along a rod, which serves as a hinge, and allowing the cover to descend, when the plates dip into the fluid, bringing themselves by their submergence into connection with the preceding cell. By reversing this procedure the plates are removed from the cells, being finally received into drip-cups, where they remain until used again.

The automatic connection of several cells by this arrangement obviously facilitates prompt action, and saves time, trouble, and complications likely to occur in the adjustment of key-boards and switches. If desired this battery can, by a slight change in the connections, be converted from a series of cells into one giving the effects of a single cell, and therefore appropriate for running low-tension motors. By another arrangement I am enabled to utilize the current from a stationary gravity galvano-cautery battery.

The employment of small nasal drills, already referred to, I desire to lay particular stress upon, as constituting a desirable digression from the routine course heretofore pursued, of resorting to large and cumbersome devices of the kind in operations upon the nose. To facilitate the practice of keeping the parts operated upon constantly in view, the dimensions of the drill must necessarily be made small. When large drills are employed, the ingenious shielded multiple knife of Dr. Goodwillie, for example, so effectively employed by him, a view of the field of operation is rendered difficult or impossible, and the operator is compelled to rely upon his acquired *tactus eruditus*, to the exclusion of his sense of sight.

The long practice required to attain the necessary tactile proficiency to operate with precision, though blind to the exact behavoir of the drill, it seems to me, must seriously interfere with the extensive adoption of large nasal drills in general practice. Furthermore, surgeons will naturally hesitate to permit keen-edged cutting instruments to rapidly revolve out of sight in close contiguity to the brain, beneath the frail plate of the ethmoid.

Fig. 2.

The extreme narrowness of the superior meatus makes it impossible to satisfactorily employ shielded drills in this region.

Although keeping for convenience a number of nasal drills of different shapes and dimensions, I shall largely confine myself to the description of two of these, namely, my rasp drill and nasal plane. The rasp drill (Fig. 3) is

Fig. 3.

virtually a hollow file, the teeth of which have been made to project, in the form of diminutive knife-points, for the distance of one-sixteenth of an inch above the circumference of the tube. These pyramidal teeth are cut at intervals of one-eighth of an inch along the circumference of the steel tube, and their relation to each other is so adjusted that a simple rotation of the instrument produces an incision resembling that made by the cut of a continuous knife-edge.

A vent-hole, cut at the distance of an inch from the tip of the drill, permits the detritus to escape and thus prevents clogging of the steel teeth, an objection met with in many cutting devices of the kind, and at the same time frees the parts from the tissue débris which is apt to accumulate and obscure the field of operation. The extremity of the drill may be capped by a crown-knife, to prevent the eroded tissues from escaping into the nostril, and at the same time furnish an effective direct drill. These little tubular drills are capable of cutting through the densest cartilaginous or osseous structures found in the nostril, with great rapidity and perfect precision. Several forms of these nasal drills are constructed, the difference depending upon the length of the teeth.[1]

In the tubular scissors or nasal plane (Fig. 2) I have

[1] An ingenious application of the trephine, shown to me by Dr. H. Curtis, and employed by him in conjunction with an electric motor, deserves especial mention. The removal, by this small drill, of the mucous membrane over the deflected septum I do not deem an objection to its use in cases where the vomer is the seat of the deflection, since the preservation of the pituitary membrane to facilitate rapid healing at this remote point, can hardly compensate for the time and labor required to attain the object. I shall therefore promptly add this useful instrument to my operative armamentarium.

utilized a cutting device which has been already employed in other parts of the body in various forms and for different purposes. It consists of a small cylinder within which rotates a delicate tube, the end of which can be discerned through the fenestra as shown in the figure. The inner tube, it will be observed, is set with a row of fine teeth. These teeth, if deemed desirable, can be dispensed with

A useful feature of these drills will be recognized in the property they possess of removing bone and cartilage of the deflected septum without injury to the overlying mucous membrane. It is obvious that the preservation of the pituitary membrane in its entirety and integrity affords protection to the wound, and hastens the restoration of the injured tissues to their proper functions. It will often be found convenient to separate the mucous membrane and temporarily secure it to the roof of the nostril by means of cotton pledgets before cutting away the subjacent bone or cartilage.

The hand-piece employed by me (Fig. 1) as a drill-holder, invented by Mr. Weber, has the great advantage of clutching the drills after the manner of a powerful chuck. A right-angled adjustable gearing device can be made by means of a sleeve to slip over the top of the hand-piece. The right angle will be found useful for keeping the drill's point constantly in view while operating in the deeper portions of the nasal cavity. It is larger and more powerfully constructed than those usually employed by dentists. A useful addition to the hand-piece will be observed in the illustration (Fig. 1) in the shape of an adjustable spray-producing device, invented by me to facilitate the practice of keeping the drill in sight. It accomplishes this result by showering the wounded tissues with cleansing fluids, or by means of the air-douche alone, while the drill is in full action. The force of the compressed air, charged with moisture, impinges upon the cut and bleeding tissues, whipping the blood-clots far beyond the field of operation. In obtaining this result I have found it necessary to branch off from the usual methods adopted for projecting sprays, on account of the obstruction that would be ordered by the fluid receptacle. The change consists in an extraordinary lengthening of the fluid conduit. This was accomplished by means of a fine rubber tubing, two or three feet in length, beginning in the spray tube and ending in the fluid receptacle. The air and fluid tubes are joined together for almost their entire length. An adjustable cut-off slipping over the head of the hand-piece enables the operator to regulate the spray at pleasure. The spray-tube proper is attached to a ring which revolves around the drum of the right angle. This arrangement renders it possible to direct the spray in any desired location about the drill. I employ the same device to produce and keep up rhigolene or cocaine anæsthesia.

I shall conclude with a brief description of two illustrative cases, selected from a number of the kind, as good examples of the results obtained by the employment of the electric motor and drills. The first case, a broker's clerk, aged twenty, referred to me by a patient upon whom I had successfully operated, consulted me in October, 1885. The patient proved to be an habitual mouth-breather, and did not remember ever having breathed freely through the nostrils. He was often deprived of needed rest by being awakened during the night with a parched throat. The accumulation of thickened mucus in his nostrils was a source of constant annoyance. He also complained of tinnitus aurium.

Examination.—An inspection of the anterior nares showed pronounced distortion of the septum in the shape of an extensive general deflection of the triangular cartilage to the left, also a localized deviation of the columna to the right, as shown in Fig. 4, taken from a life-sketch. The displaced cartilage pressed firmly against the inferior turbinated tissues in the left nostril, producing complete occlusion on this side.

The right nostril, though only partially obstructed by a localized deviation of the septum, associated with an inferior turbinated hypertrophy, possessed very little respiratory value. Without entering into the details recorded in my case-book, I will simply state that the careful employment of the electric motor and drills, in conjunction with my stellate punch, cartilage, and bone-trimming forceps, resulted in the satisfactory correction of the deformity, the complete restoration of nasal respiration, and normal nasal drainage, and the consequent disappearance of all the annoying symptoms.

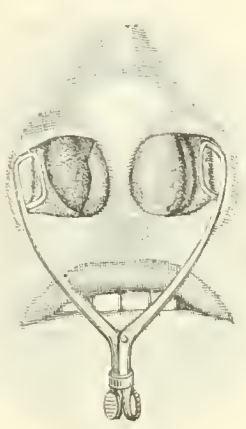

FIG. 4.

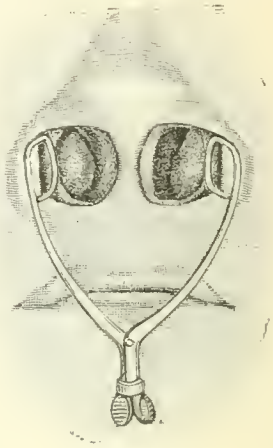

FIG. 5.

Fig. 5, drawn from a life sketch, taken five months subsequent to the operation, shows the appearance of the parts after complete healing had occurred.

The next case I shall present is that of a druggist, aged twenty-seven, who consulted me February 17, 1887, in search of relief from a difficulty in breathing. The left nostril was permanently stenosed, and the right one, though partially free, would become periodically obstructed, and was a source of constant annoyance.

Examination.—Anterior rhinoscopic inspection demonstrated the existence of an extensive osseo-cartilaginous deflection of the septum to the left, extending as far back as the middle of the vomer. The patient did not manifest the slightest dread in submitting to an operation in which the electric drills were employed. The osseous and cartilaginous tissue was first cut away with the rasp drill, and subsequently smoothed down by means of the revolving nasal plane. Forty minutes were consumed in cutting a large opening from the anterior free edge of the deviated tissue, the columna, to the post-nasal opening, about the middle of the vomer. This time included intervals of rest required for spraying the parts with cocaine and noting the progress of the operation. The loss of blood was unusually scanty. One month after the operation the wounded septum had completely healed, leaving a large interspace between it and the lateral nasal wall for the entire length of the nostril. The patient stated that the great cause of his suffering, the difficulty in breathing, had entirely disappeared—nasal respiration being as perfect in the night-time as during the day.

I cannot conclude my paper without acknowledging the courtesy extended to me by Mr. W. F. Ford, while bringing my mechanical experiments to a successful issue, and I might add that any or all of the devices described by me can be obtained from Hazard & Hazard, of New York.

Professor Pean, like Bergmann and Guyon, performs the suprapubic section for stone. Every teacher and operator I have seen in Europe discards the perineal section. Crushing small calculi and removing larger ones by the high operation seems to be almost a universal rule at the present time.—Cor. *Chicago Medical Journal.*

Progress of Medical Science.

Creatinin in Normal and Pathological Urines.—In opposition to the assertion of Professor Hoffmann, Grocco finds that muscular work has a direct influence on the quantity of creatinin eliminated by the urine (*The London Medical Record*, February 15, 1887). He finds that whenever muscular work is considerably increased the quantity of creatinin eliminated is also increased. Even in the urine of babies in the first few months of life, and fed exclusively on milk, creatinin may be found, though in very small quantity. Fever in general leads to increased creatininuria. The relation between the degree of fever and the quantity of creatinin is not, however, constant. In adynamic forms, or with renal complications, the creatinin diminishes. The alimentation also influences the quantity eliminated. In forms with rapid wasting the creatininuria is more marked. Hydræmia and cachexia lead to the diminution of the creatinin, but in every case the cause and progress of the anæmia must be taken into consideration, since with an equal degree of anæmia the creatinin may be excreted in very different quantities, and in even grave anæmia there may be an increase due to the presence of fever. Jaundice does not lead, at least necessarily, to diminution of the creatinin in the urine. In heart-disease there is diminution in the last stage of cachexia; with commencing loss of compensation the creatinin may be increased. Diffuse parenchymatous and interstitial nephritis cause diminution of the creatinin. In three cases of diabetes mellitus there was slight diminution also. In nerve diseases with much muscular agitation the creatinin increases, in others with immobility it tends to diminish. Amyotrophic paralysis of spinal and peripheral origin (poliomyelitis, atrophy, and progressive muscular pseudo-hypertrophy, primitive multiple neuritis) gives a general diminution of creatinin when the muscular atrophy is sufficiently extensive; but if the atrophy takes place rapidly and tumultuously the creatinin may be increased.

The Employment of Electricity in the Treatment of Diseases of the Genito-urinary Organs.—Dr. Steavenson states that the results obtained by the treatment of the genito-urinary organs by electricity are most satisfactory. The lowest centres or points for the reflection of impulses connected with the genito-urinary apparatus are situated in the lumbar enlargement of the cord, and by placing one electrode on the spine over the lower dorsal region and the other to the affected organ the whole nervous supply of these parts can be included in the circuit. Cases of nocturnal incontinence in children, in which no reflex cause can be found, are often cured by passing a weak current through the region of the bladder. A pad, connected with the negative pole of the battery, is placed over the dorsal region of the spinal column, and a small button electrode on the perineum. By placing the negative electrode on the back a stronger current can be borne than if the button in the perineum were made negative. In cases of simple incontinence of urine, when the sphincter is not at fault, and when the affection is due to loss of power of inhibition during sleep, or to paralysis of the muscular coats of the bladder from over-distention or other causes, then one electrode may be placed over the pubes. In cases, however, where there is weakness of the sphincter, unless an electrode is placed in the urethra itself, the best place is without doubt in the perineum, as the sphincter vesicæ does not get included in the circuit when the electrode is placed over the pubes. Undue frequency of micturition is also relieved by galvanism, and when this is due to cystitis the electric current produces a healthier condition of the bladder-walls, causing an improvement in the frequency of micturition. Neuralgia of the pudic nerve is often relieved by galvanism. In the application of electricity to the bladder for atony, incontinence, or frequency of micturition, a current from two to five milliampères, applied for eight to ten minutes every day, or every other day, for about ten days, is all that is generally required. One of the most useful applications of electricity is in the treatment of stricture of the urethra by electrolysis, but the elaborate apparatus required prevents its general use. By this method a stricture can be, as it were, absorbed without any bleeding. If hæmorrhage does occur it is accidental, and usually shows that a too strong current or the wrong pole of the battery has been used. No anæsthetic is required, as the discomfort is trifling. After electrolysis has proceeded so that the electrode will pass into the bladder, it is found a fortnight later that a bougie of two sizes larger can be passed. In penile strictures it will be noticed, after treating them by electrolysis, that a few days afterward no hard, dense tissue can be felt. The author strongly advocates this method of treatment.—*The British Medical Journal.*

The Microbes of Suppuration.—Dr. Kranzfeld has given much attention to this subject, experimenting upon animals, and also making numerous clinical observations. The conclusions at which he has arrived are as follows: 1. In the pus in cases of acute suppuration micro-organisms can always be demonstrated both by cultivation and by the direct examination of the pus. 2. The micro-organisms most commonly met with are staphylococcus pyogenes (aureus, albus, and citreus) and the streptococcus pyogenes. 3. The presence and the development of micro-organisms in the tissues must be regarded as the principal factor in the etiology of acute suppuration. 4. Traumatism and like causes play only a subordinate part in etiology, acting solely as predisposing factors. 5. In infection, the following conditions are of importance: *a*, The quantity of micro-organisms introduced; *b*, their collection in one spot; *c*, the condition of the tissues. 6. Staphylococcus and streptococcus are two entirely different micro-organisms, both from a morphological and a biological standpoint. 7. They differ in their cultivation forms and in their relation to the tissues of the organism. 8. Staphylococcus pyogenes: In cultivation—a more rapid growth and a good development independent of access of air; in the tissues—a rapid development, probably through the medium of the blood. 9. Streptococcus pyogenes: In cultivation—a slower growth and a more feeble development, that proceed better without free access of air; in the tissues—a slow development and localization especially in the lymph-channels. 10. In the great majority of acute local suppurations the micro-organisms enter through external wounds. 11. In some cases a general infection of the body occurs through a distant external lesion. 12. The phlegmon due to staphylococcus pyogenes occurs at the seat of the injury. 13. The phlegmon due to streptococcus pyogenes occurs at a distance from the seat of injury, following the lymphatics. 14. Both staphylococcus pyogenes and streptococcus pyogenes can lead to general infection (pyæmia, septicæmia). 15. In the general infection from staphylococcus pyogenes the metastatic collections are especially localized in the internal organs; in that from streptococcus pyogenes in the joints and serous membranes. 16. During the period of the development of the skeleton if there be a general infection from staphylococcus aureus there is a disposition for the collections to be localized in the organs of locomotion, notably in the bones.

How to Purify Drinking-water.—Professor Dobroslavine, of St. Petersburg, recommends as a means of purifying (clarifying?) drinking-water, the addition to each twelve litres of water of fifty centigrammes of perchloride of iron and seventy centigrammes of crystallized carbonate of soda. He claims that the precipitate thus formed carries with it all suspended impurities, leaving the water, after forty-five minutes, perfectly clear.

THE CHARACTERISTC KIDNEY INFLAMMATIONS OF SCARLATINA.

IT has been quite well determined by modern researches that the scarlatinal poison produces certain inflammatory changes in the kidneys which are peculiar and striking in character. An excellent review of this subject of scarlatinal nephritis is given by Dr. Frank Grauer, in the February number of *Gaillard's Medical Journal.*

Three forms of nephritis have been found associated with scarlatina:

First, the initial catarrhal nephritis; second, the large, flabby, hemorrhagic kidney; third, acute glomerulo-nephritis, or nephritis post-scarlatinosa.

The initial catarrhal nephritis is the form met with in the first week of the disease, generally accompanying the exanthema, lasting from a few days to a week, and then gradually disappearing. It rarely leads to death. It is only recognized by a chemical and microscopical examination of the urine, in which one finds a slight amount of albumen, mucus, and hyaline casts; more rarely, red and white blood-corpuscles, renal epithelium, and granular casts. There are very rarely any symptoms pointing toward kidney trouble, and if any are present, they are liable, in the majority of cases, to be overlooked, or else attributed to the febrile condition.

The kidneys in this type are enlarged and hyperæmic, with thickened cortex and some loss of striæ.

The large, flabby, hemorrhagic kidney is quite rare. Friedländer found it present in only twelve cases out of the two hundred and twenty-nine that he examined. It generally occurs between the first and the fourth week of the disease. It runs a rapid course, and in some cases the urine is normal up to within twenty-four to forty-eight hours before death. Œdema rarely occurs. This form of nephritis is generally found in those cases accompanied by extensive angina and diphtheritic inflammation. The kidneys are enlarged and softened. The cortical substance is thickened and grayish-red in color. There is complete loss of the striæ, and the glomeruli, as a rule, are invisible. The cortex is studded with ecchymoses and large hemorrhagic infiltrations.

The most frequent and characteristic type of scarlatinal nephritis is the acute glomerulo-nephritis. This form is almost characteristic of scarlatina, and occurs in other diseases only very rarely.

Glomerulo-nephritis generally occurs in the third or fourth week of the disease, the patient being convalescent and the urine normal. Then unexpectedly some œdema appears about the patient's eyes. The urine is now found to contain albumin and to be turbid, diminished in amount, of high specific gravity, and microscopically to show epithelium, blood-cells, and hyaline casts. The disease may progress to recovery in a few weeks or may get progressively worse, uræmia setting in and death finally occurring.

Dr. Grauer gives a *résumé* of Klebs' observations, to whom is due the credit of first observing that the glomeruli are affected in scarlatinal nephritis. A review of the present knowledge of the minute anatomy of the renal tubules is also given. The description is correct in its anatomy, though deficient in syntax, the writer not being able to rid his mind of the idea that *vasa efferentia* is a noun in the singular.

The descriptions of the microscopical appearances in glomerulo-nephritis as observed by Klein, Ribbert, Klebs, and Langham are given, and to them are added the results of observations made on nine cases of glomerulo-nephritis by the writer himself. The morbid anatomy of the disease is summarized as follows. The kidneys are enlarged and hyperæmic; there is no loss of cortical striæ, and in some cases the cortices may be somewhat thickened. The glomeruli are pale, prominent, and more or less enlarged. As regards the microscopical examination, the uriniferous tubules are apparently normal. There may be some evidence of a slight parenchymatous inflammation, the epithelium may be somewhat swollen, and occasionally one may see a cast in the tubules. The following changes are found in the glomeruli: They are bloodless. One very rarely sees a red blood-corpuscle in the lumen of a capillary, especially when stained with hæmatoxylon and eserin. If present they would be stained a rose color by the eserin. When examined with a low power, the glomeruli are found larger than normal and covered with a mass of nuclei. With an immersion lens the following changes are noticed in the capillaries: In some capillaries the only change that is noticed is a thickening of the endothelial layer, which becomes more granular. In others the lumen of the capillary is filled with a rich nuclear protoplasm, which is probably composed of the nuclei of proliferated endothelial cells.

SALICYLIC ACID IN METRORRHAGIA.

THE latest remedy for uterine hemorrhage which is mentioned in current literature is salicylic acid, and if it acts with as great rapidity and certainty in other cases as it is reported to have done in two, it would seem to be a valuable addition to the list of uterine hæmostatics.

Dr. Alessandro Felici reports two cases in the *Gazzetta degli Ospitali* of March 6, 1887. The first was a case of hemorrhage in cancer of the uterus, in which all the known remedies had been tried without success. By means of a pledget of carbolized cotton, moistened with a solution of salicylic acid, the writer succeeded in arresting the hemorrhage within a few minutes. The other case was apparently one of simple metrorrhagia, occurring at the menopause. The woman, when first seen, was in a state of collapse from the loss of blood.

Dr. Felici tried first the approved remedies, and succeeded in controlling the flow of blood for a time; but the hemorrhage returned again and again. Finally he took a piece of cotton on a uterine probe, and, dipping it in a strong solution of salicylic acid, introduced it into the uterine cavity. In a few moments the hemorrhage ceased and did not again return.

Although these two cases by themselves do not prove much, they may, perhaps, be worth remembering in case of trouble from uncontrollable uterine hemorrhage.

AUTO-INTOXICATION IN RELATION TO DISEASE.

THE medical world of France has been much interested and, indeed, profoundly moved by the contributions to the subject of ptomaines, leucomaines, microbic poisons, and other toxic substances developed in connection with animal life. M. Peter and not a few others see a new era in medical pathology and practice opening up before them. We have at various times alluded to this subject, which is now brought up again by the publication of the work of Bouchard: *Auto-intoxication dans les maladies*, Paris, 1887.

Professor Bouchard bases his work on the researches of Selmi, Gautier, Brieger, and others, as well as extensive investigations made by himself. The fundamental principle which he elaborates is, that the human body, both in health and disease, is a receptacle and a laboratory of poisons. These poisons are derived from the digestive changes in food, from the fermentations, putrefactions, and other microbic processes in the alimentary tract, as well as from the retrograde changes in the tissues. These poisons, though being constantly elaborated, do not affect the general system, in part because the liver protects it, destroying the toxic matters as they are carried to it by the portal blood. In part, also, the system is protected by the emunctories. So far, Professor Bouchard announces nothing especially new; and it is only in the details which he believes himself able to give that any advance in our conceptions of nutrition and excretion is seen.

The French professor is nothing if not precise, and so Bouchard finds precisely seven different toxic substances in the urine; one is a diuretic substance, the second a narcotic, another is a sialagogue; one contracts the pupil, one is antipyretic, and two are convulsive. These poisons come from the blood, and are being constantly drained away by the kidney. They exist in the plasma in such amount that a man would die poisoned by his own blood if it contained ten times more than normal.

The contents of the intestines are particularly poisonous, the toxicity of the fecal matter being due to the potash, the ammonia, and the alkaloids. By intestinal antisepsis the poisonous alkaloids both of the fæces and the urine disappear; an important fact, if true, since it points to a helpful mode of treatment in renal disease.

The cause of uræmic poisoning is quite well settled, apparently, in Bouchard's mind. It is due to a number of toxic substances which unite to produce the pathological condition. They exist in the following proportions: Coloring matters, $\frac{3}{10}$; extractions, $\frac{1}{10}$ to $\frac{2}{10}$; potassium and other mineral matters, $\frac{4}{10}$ to $\frac{5}{10}$. The variety of symptoms in uræmia is due to the preponderance of one or other toxic substance.

Our author has also studied the conditions of constipation, *embarras gastrique*, intestinal obstruction, and especially dilatation of the stomach in which there is an excessive fabrication of poisons. According to Bouchard, dilatation of the stomach may cause not only the ordinary dyspeptic and nervous symptoms, but also a peculiar form of albuminuria, a kind of osteo-malacia, a variety of nodular rheumatism, and perhaps of rachitis. Naturally, in the infectious diseases, particularly typhoid, auto-intoxication plays an important part.

Icterus is another form of auto-intoxication. Here the poison consists directly of the coloring matters of the bile, and indirectly of the biliary salts. The free action of the kidneys alone saves the organism from rapidly fatal death. Acute yellow atrophy and acetonæmia are other illustrations of the auto-intoxications of a severe type.

A chapter is devoted to the subject of therapeutics. The practical outcome of Bouchard's researches is quite in harmony with the experience of ages, for it teaches the importance of keeping the emunctories open and of avoiding harsh, or easily fermentable foods. In addition, great stress is to be laid on intestinal auto-sepsis and the avoidance or cure of dilatation of the stomach.

MATERNITY HOSPITALS THAT NEED REFORMING.

IF Dr. Herst's statistics, published in the *Medical News*, are correct, there is need of a very radical change in the methods followed by obstetricians and lay managers connected with some of our large maternity hospitals. For example, the death rate from all causes in five hospitals, according to Herst, in 1885 was:

Louisville, City Hospital.....	3.75	per cent.	of women	confined.
Indianapolis, City Hospital.....	4.71	"	"	"
King's County Hospital, L. I...	4.76	"	"	"
Brooklyn Maternity	4.44	"	"	"
New Orleans, Charity Hospital.	10.22 (!)	"	"	"

"This last record," adds the doctor, "reminds one of the days when Semmelweiss was struggling for reform in the Vienna Hospital, or when Tarnier first took charge of the Maternité."

Certainly, in the light of modern knowledge, it is little short of murder to allow a three and four per cent. mortality in a lying-in hospital, except there occur some exceptional and unavoidable accidents. We trust, and are quite willing to believe, that some explanation can be given for the extraordinary mortality-rates cited above.

THE TEMPERATURE OF DWELLING-ROOMS.

DR. D. BENJAMIN, of Camden, N. J., has made some observations regarding the subject of the varying temperature of our dwelling-rooms which will be found of much practical importance (*The Sanitarian*).

Everyone knows in a general way that the air of rooms is colder near the floor and near the windows, but the very exact differences of temperature as obtained by Dr. Benjamin are very striking. For example, in a room ten feet high, twelve wide, and twenty long, with a good stove and steady fire the temperature in the centre was found to be 78° F.; four feet from the window it was 70°; one foot from the window 54°, and

at the window 40°. At the height of the head the temperature was 75°, at the floor 50°, a difference of 25°. At the ceiling the temperature was 90°, when the temperature at the height of the head was 70°.

The experiments cited above were made in a three-story brick house of twelve rooms, with a warm cellar. It was further observed that when the three floors were as nearly as possible evenly heated, the second floor had a much more uniform temperature than the first or third.

The fact that the temperature of dwelling-rooms varies so widely explains, no doubt, the frequency with which young children, and even adults, take cold in the house. A child sitting on a nurse's lap in a temperature of 70° gets down and plays on the floor in a temperature ten or more degrees lower, or runs to the window, a change of twenty or thirty degrees. The habit which ladies have of wearing slippers or light shoes in the house is the cause of many troubles, for these same reasons.

The temperature of a room should be about 70° F. The hot furnace-heated houses of our cities cause a vast deal of nervous and respiratory trouble. The thermometer should be hung at about the height of the person's head, and, of course, not near the window or the stove.

Dr. Benjamin adds: "Some years ago I devised a contrivance to protect children from the death-dealing windows in cold weather, which has given me, as well as parents, much satisfaction. It is simply a fender of metal (also made of wood) about three feet high, and extending out from the window fifteen or twenty inches.

In some families where I have had these screens arranged to the windows for one or two years I have reduced the medical attendance very greatly, as my books will show.

DIABETES.

The death of prominent men from diabetes seems to be an increasingly frequent event, and the general impression prevails that diabetes, of neurotic origin especially, is commoner than it was formerly. This is probably the case, yet the statistics of the United States censuses for 1870 and 1880 do not show any striking change. In 1870, for example, the number of deaths from diabetes reported was 837, or .17 per cent.; in 1880 the number was 1,443, or .19 per cent. of the total deaths.

The fast life of the American, the accumulation of wealth, and indulgence in excessive drinking and eating would explain in part an excessive increase in diabetes. Glycosuria is said to be very prevalent in the Northwest where the air is very dry, where business competition is exceedingly keen, and where nervous wear and tear are great.

Diabetes is a disease which has many specifics, and recently we have had a new one given us based on extensive trial of ten years.

The account of it is given by the Paris correspondent of *The Lancet*, as follows:

"At a recent meeting of the Société de Thérapeutique, M. Martineau stated that he had been treating diabetes for the last ten years, with almost invariable success, by a method which he had borrowed from a practitioner now dead. He had hitherto made no communication upon the subject, because he had wished to be perfectly certain that his conclusions were not premature. The treatment consists in the administration of a solution of carbonate of lithia and arseniate of soda in aerated water, to the exclusion of all other drinks. Besides taking this with his meals, the patient uses the same as a beverage when thirsty at other times. M. Martineau affirms that this regimen has cured sixty-seven of seventy diabetic patients he has had occasion to treat."

SANITATION AND POLITICS IN SAN FRANCISCO.

The *Pacific Record of Medicine and Surgery* has been making some serious charges against the city officials of San Francisco. It claims to have proved that the large amount of the city's milk-supply comes from diseased cows, that the bacilli tuberculosis have been detected in the milk distributed, and a diphtheria epidemic is now present and is killing a dozen children a week. This, it is claimed, is largely due to defective plumbing and sewerage. The sewers were built by contract with political hacks, contracts in which the money was divided before the work was done. "The owners of the dairies where sick cows are milked, for the sustenance of infants and invalids, are also the owners of distilleries, in many cases, and *must* use their refuse. Thus we see how rum and politics conflict with sanitation."

There is some difference of opinion, evidently, about the cause of the diphtheria. One of the members of the City Board of Health advances the ingenious theory that it is due to the children "swapping gum."

Unfortunately for this theory, says the *Pacific Record*, the fatal cases occur mostly among infants too young to swap anything but unretained mother's milk.

Our Pacific contemporary is, so far, rather ahead in the controversy; although we are not denying that the practice of "gum swapping" may be a powerful promotor of diphtheria.

THE MORTALITY IN AMERICAN AND EUROPEAN LYING-IN HOSPITALS.

In a recent letter to the *Medical News* Dr. H. J. Garrigues, of this city, shows that certain statistics published by Dr. Hirst do not give a fair idea of the death-rate in American lying-in asylums (placed by Dr. Hirst at 2.59 per cent.). In the past three years, for example, under strict antisepsis, at the Maternity Hospital on Blackwell's Island, the mortality rate has fallen from 4.40 per cent., the average in four preceding years, to 1.06 per cent., the average since 1883; while the mortality from sepsis has fallen from 2.98 to 0.33 per cent.

In general terms it is thus seen that the mortality-rate from childbirth has of late years fallen in our better public institutions from four to one per cent. In many of the smaller and well equipped institutions in this country the results are much better even than this; so that, on the whole, American obstetrical work compares very well with that of Europeans. As an illustration of what can be done, it may be stated that in the last four years there have been nearly one thousand confinements in the Emergency Hospital of Bellevue without a single death from puerperal infection.

News of the Week.

Dr. Peter Eager, a prominent physician of Wyandotte, Kan., died recently of pneumonia. He was a member of the State Board of Pharmacy. He formerly lived in Newburg, N. Y., and in this city.

A Patriotic Dentist in Germany announced his intention of extracting teeth and supplying false ones, gratis, to all comers on the occasion of the Emperor William's birthday.

Sun Spots and Apoplexy.—A Rochester astronomer states that he has observed that during solar disturbances there are many sudden deaths from paralysis and apoplexy.

Sir James Paget on Mastication.—In a recent address on dental surgery, Sir James Paget dwells upon the high functions of the molars, which, he says, stand half-way between the dead and the living—that is to say, between the food to be consumed and the tissues formed by it. Upon them depends very greatly the character which will be given to those tissues. In other words, the mode in which we masticate has an appreciable effect upon our future physical condition. "Who knows how much those thirty-two bites which Mr. Gladstone is believed to take at every piece of meat which he consumes may have had to do with his bodily system, and hence, by no means indirectly, with the Irish question!"

Venereal Disease and the Bible.—Probably none but a Frenchman, with the dominating sexuality of his race, would take the trouble to go through the Bible, verse by verse, hunting for evidences of venereal disease among the Hebrews of the biblical epoch. This has been done by Dr. P. Hamonic, of Paris. He discovers evidences of onanism; thinks that the *mal des Philistines* was proctitis, provoked by sodomy; believes that Moses "differentiated perfectly" spermatorrhœa from blennorrhagia, and that Herod died of a phagedenic chancre.

Nine Hours' Artificial Respiration.—Reports from Ceylon contain an interesting description of recovery of consciousness of the taxidermist of the Victoria Museum, who was bitten by a cobra, which he thought harmless, from previous extraction of the poison-bag. For a few moments after the bite he took no heed of it, but pain and nausea were soon set up. Carbolic acid was then applied, ligatures were bound round the arm, an incision was made at the bite, and the blood of the arm was wholly removed. Various antidotes were used, but the unfortunate man lost the power of speech, and soon every muscle became paralyzed, and respiration ceased. Artificial respiration was then resorted to, and this operation was unceasingly continued for nine hours, when at last the patient made an attempt to breathe, and soon regained consciousness enough to make his wants known. He steadily improved until Friday, the accident having taken place on Wednesday, and then astonished those around him by stating he was conscious of all that had been taking place, but was unable to make his feelings known, not having the power to move a muscle.—*Medical Press and Circular.*

The Etiology of Scarlet Fever.—The chain of evidence connecting human scarlatina with a certain disease (as yet unnamed) occurring in milch cows has been made remarkably complete and unbroken by the renewed researches undertaken for the British Government by Dr. Klein. It may be remembered that a specific and distinct micrococcus was isolated from the ulcers of the cow, and that this, when inoculated into calves, produced morbid lesions exactly like those of the cows at Hendon, and those usually found in human scarlatina. During the present winter Dr. Klein has examined the blood of scarlatina patients at the Western Hospital, Fulham, with the result of finding in it a micrococcus identical as to growth and cultivation with that obtained from the cows' ulcers. He further found that on inoculating and feeding mice with the two sets of micrococci, viz., Hendon and Fulham, the same pathological results were produced. And, lastly, cultures were established from the blood of mice which had perished after these inoculations; and these were found to contain the same micrococci again, growing in exactly the same manner. Similar inoculations were made on calves, which developed similar lesions to those affecting certain calves inoculated with the Hendon micrococcus last year; and from the heart's blood of these the same micrococcus was recovered by cultivation, as has been found in the Hendon cows' ulcers and the fever-patients' blood. Thus, then, the circle has been fully drawn; and a valuable discovery lies enshrined within it, one which reflects the greatest credit upon the perspicacity of Mr. W. H. Power, who made clear the circumstantial details of the Hendon outbreak, as well as the skilful and philosophic experimentation of Dr. Klein. But the practical importance of this newly observed relation between scarlatina and cow-disease transcends its mere scientific aspect, for there is obviously power, by careful supervision of herds and of dairies, to limit and curtail the action of the most blighting influence against which our youthful population has to fight. —*Medical Press and Circular.*

The Albany Medical College held its Annual Commencement on March 16th, and conferred degrees upon a class of thirty-seven.

Fasting in the Interests of Science.—On March 11th a Norwegian, F. Cetti, began a thirty days' fast under the supervision of Virchow, Senator, Zunz, and other medical men.

The Central College of Physicians and Surgeons of Indianapolis held its eighth Annual Commencement on February 28th, and graduated a class of four.

The Atlanta Medical College conferred degrees on forty-five graduates at its Commencement, March 4th.

The Medical Association of Alabama meets at Tuscaloosa on April 12th.

The Southern Medical College of Atlanta held its Annual Commencement on March 3d, and graduated thirty students.

The Medical Society of the State of North Carolina will hold its annual meeting at Charlotte on April 13th, 14th, and 15th.

Suicide of a Doctor.—Dr. A. G. Ely, of Girard, Penn., committed suicide by taking an overdose of morphine on March 27th. The doctor was one of the leading physicians and surgeons of Northwestern Pennsylvania, and had amassed a fortune of $150,000. The delusion that his property was getting away from him drove him to self-destruction. Dr. Ely was sixty-seven years of age, was a graduate of Hamilton College, New York, and graduated from Geneva Medical College in 1841.

The Medical Society of the County of New York, at the stated meeting held Monday evening, the 28th inst., unanimously indorsed the Senate Bill, No. 391, entitled "An Act to regulate the Licensing and Registration of Physicians and Surgeons, and to codify the Medical Laws of the State of New York;" and urged all its members to be active, with their personal influence and correspondence with members of the Legislature, in favor of the Act becoming a law, as it was opposed chiefly by one notorious quack residing in the city of New York. Make it a personal matter not to be outfooted.

Laws Regarding Color-blindness in Alabama.—The last Legislature in Alabama passed an act compelling all railroad employés engaged in any manner in the running of trains to be examined for color-blindness and defective sight. As a Board of Examiners the Governor has appointed Drs. Benjamin J. Baldwin, of Montgomery; W. D. Webb, of Birmingham, and W. H. Saunders, of Mobile.

Certificates of Illness.—We learn from the *Boston Medical and Surgical Journal* that the Faculty of Harvard College has promulgated the extraordinary rule that in all cases in which the college has heretofore required a physician's certificate to the fact of illness of absent students, such certificate must specify the cause of illness, in order that the Faculty may be able to judge of the validity of the excuse for absence. The *Journal* says that such a requirement is unjust to the physician and student. No doubt this is true, yet we fear that such a regulation would never have been made if Boston and Cambridge physicians had not got into lax habits in the matter of giving certificates.

A Medical Speaker.—Dr. Baxter has been elected Speaker of the Ontario Legislature.

Thirst in Diabetes.—Duchenne recommends (*Nouveaux Remèdes*) the administration, three times a day, of a drachm of a solution of potassæ phosphas, two parts in seventy-five parts of water. It is best given in a little wine or hot tea.

The Late Dr. John W. Russell.—Very fitting resolutions of respect to the memory of the late Dr. Russell were adopted at the last meeting of the Knox County Medical Society.

Homœopathy at Ann Arbor.—We are pained at the lightness and jocosity with which our esteemed contemporary, the *Medical Age*, treats the profound ethical questions arising periodically at Ann Arbor. The present trouble there, we are told, is again due "to the complex or duplex system of teaching homœopathic and 'regular' students. Homœopathic and 'regular' anatomy, physiology, etc., being supposed to be identical, the homœopathic department at the university is not furnished with chairs on these subjects, and its students are sent across the campus to take them in the regular way at 'regular' hands. This they do not seriously object to, but they do desire, very much, when they are *au fait* in these particular branches, to have the 'regular' professors give them certificates to the fact. The 'regular' professors, however, find that to certify that a homœopath is proficient in these branches would be a violation of the Code of Ethics; it is enough for them to teach homœopaths, but for them to say that such teaching has been effective would be very 'irregular.' The common herd cannot, of course, comprehend the niceties of the distinctions, but that makes little difference—they can look on and enjoy the fight all the same.'

Professor H. C. Wood writes us that the statement in our issue of March 26th that he had been offered the Chair of Medicine at the Johns Hopkins University has no foundation in fact.

Professor Arlt, of Vienna, who has been suffering for a long time from severe illness, died on March 7th.

The American Dermatological Society holds its next annual meeting, at Baltimore, on August 31st and September 1st and 2d.

The American Neurological Association holds its thirteenth annual meeting at Long Branch, N. J., on July 20th, 21st, and 22d.

The Medical College of Indiana graduated a class of twenty-nine at its Commencement on March 2d.

Homœopathic Hospitals and Lay Managers.—We are not surprised that the lay managers of homœopathic hospitals should insist on having their institutions conducted on strictly homœopathic principles. It comes very near to being fraudulent when laymen are asked to support a homœopathic hospital in which the Hahnemann dogmas are neglected and all the resources of rational medicine are used. Laymen contribute to homœopathic charities because they believe in homœopathy. *À propos* of this we learn that eight of the women physicians connected with the "Medical, Surgical, and Maternity Hospitals of the Women's Homœopathic Association of Pennsylvania" have resigned because the managers have made a rule that "no medicines, except strictly homœopathic potentized remedies, shall be allowed for use in the dispensaries or in any department of the hospital."

Medicine and the Talmud.—Dr. Carl von Klein intends to publish a work on medicine in the Talmud, if he can get a thousand subscribers.

New York in 1833 contained a population of 202,957 and about 452 physicians, of whom 302 were members of the County Society. The proportionate number of doctors was quite as great, therefore, fifty years ago as it is now.

Intubation.—Dr. Joseph Eichberg, of Cincinnati, reports 6 more cases of intubation of the larynx for croup (*Lancet and Clinic*), making a total of 8 cases, with 5 deaths. Dr. Jerome A. Anderson reports 10 cases of intubation (*Pacific Medical and Surgical Journal*, March, 1887), with only 1 recovery. Dr. Anderson has done 22 tracheotomies, with 8 recoveries.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN PRACTICE.

Stated Meeting, March 15, 1887.

E. Darwin Hudson, M.D., Chairman.

Dr. C. E. Billington read a paper [see p. 397] on the

LOCAL TREATMENT OF DIPHTHERIA.

Dr. A. Jacobi opened the discussion [see p. 402].

Dr. J. Lewis Smith continued the discussion, and said he thought that most physicians would agree with Dr. Billington's view that diphtheria was primarily a local disease which became constitutional. He thought, also, that this theory had been proved by the experiments of Wood and Formad, of Philadelphia. But Dr. Smith believed that it was not invariably and *always* a local disease primarily.

In the local treatment of this affection nothing of an irritating nature should be used. Any local application that produced smarting which lasted more than four or five minutes should be discarded. It had been his custom to use very mild local remedies. He regarded the muriate of pilocarpin, so fashionable only a short time ago, as a very dangerous remedy, on account of its liability to produce disastrous œdema of the mucous membrane of the air-passages.

The nostrils, especially, required dilute solutions, and it had been his custom to use boric acid, ʒj.; borax, ʒij.; chloride of sodium, ʒj.; and water, Oj. Use warm. He recommended the use of the ordinary medicine-dropper in applying the remedy to the nostrils.

Another favorite local application consisted of lime-water, to which had been added bicarbonate of soda in the proportion of ʒj. to ℥ viij., and used with either a spraying apparatus or a brush. The sponge he regarded as altogether too harsh for making local applications, as it was very liable to remove forcibly the false membrane, which was not desirable. Probably some benefit attended the use of trypsin, and it could be added to the above alkaline solution.

Dr. F. H. Bosworth thought that the paper should be taken in connection with Dr. Billington's papers in 1875 and 1880, in which could be seen the painstaking labor bestowed upon every case. He had nothing to say in the way of criticism.

There was one predisposing cause not mentioned to which he would like to direct attention, and that was the development of glandular tumors, as enlarged tonsils, where the germ finds a favorable nidus. These, as well as mucous membrane, the seat of acute inflammation, afforded a favorable nidus for the beginning of the disease.

One of the striking features of the paper was that no specific remedies were recommended, and yet it seemed to him that an immense amount had been taught in the doctrine that

TO DESTROY THE MEMBRANE AND THE LOCAL AFFECTION WAS TO DESTROY ITS POWER FOR EVIL.

With regard to the local use of remedies in the nasal passages, the syringe, even in the hands of trained nurses, often involved a certain amount of danger, while the use of spray was attended with no danger, and nothing was better for the purpose than the Millard atomizer, No. 5.

He regarded the use of the galvano-cautery as utterly absurd, for "destructive potency" existed in other agents which could be more safely employed. He would reject carbolic acid, and use an agent that kills the germs. Pilocarpin, also, he regarded as most absurd.

Dr. D. Bryson Delavan said that no one better than Dr. Billington knew how highly he appreciated his service in the treatment of diphtheria, and he also mentioned that a professional friend had told him that he had saved more patients during the last five years, since reading Dr. Billington's papers, than he had saved in all his practice before that time.

He saw no reason why carbolic acid was safer, but many reasons why it was inferior to bichloride of mercury, which in his hands had been productive of more good than any other drug. He believed it to be best to spray the nostrils, even though there were no manifestations of diphtheria within them. He preferred to use spray because it was less harmful when used carelessly, and when used carefully it was as efficient as injections. Trypsin was a slow solvent, but he had used it with more or less good results. Still, to rely upon it might be to neglect proper disinfection of the throat and nose.

Dr. T. J. Hutton, of Fergus Falls, Minn., was present, and on invitation gave his views concerning the treatment of diphtheria by the local use of

SOLUTIONS OF NITRATE OF SILVER.

He believed that there were probably fifty remedies that would cure diphtheria if we only knew how to use them. Nine years ago he hit upon a plan of treatment which had served him so well that in 209 cases only 12 patients had died. He claimed that it could be *demonstrated* that diphtheria was a local disease, and that by his treatment it could be arrested. The only limitation or modifying condition rested in the question whether or not diphtheria was the same everywhere. He was not positive on this point, but believed that it was the same wherever it occurred. It might be that country districts furnished greater resistance to the disease than did cities, and hence there might be an apparent difference. But, in the locality where he was practising, with diphtheria as he had seen it, he believed that the treatment which he had used was infallible when the patients were seen in the first stages of the disease, and that it saved to the uttermost in the septic cases. Nothing was claimed for the treatment in cases of stenosis.

There were two indications to be met in the treatment.

First, the disease was local at the beginning, and the indication was to destroy the false membrane and keep it destroyed.

Second, the disease manifests vital depression speedily, and therefore the patient must be supported by all possible means.

To meet the first indication he uses *lunar caustic* in solution, varying in strength from twenty to fifty grains to the ounce of water, applied with a camel's-hair brush, and applied so long as any membrane continues to form.

THE CHIEF POINT TO REMEMBER WAS THAT THE MEMBRANE SHOULD BE DESTROYED COMPLETELY.

The use of the remedy in this way was not painful. Besides this he uses chlorate of potash in cases in which the patients can gargle: ℥ iss. of potash to ℥ viij. of water, and gargle every fifteen minutes; or, if the patient be too young to gargle, administered internally.

Abundant supply of fresh air. If this cannot be obtained in-doors, take the patient out-of-doors. Keep the patient *in the recumbent posture in bed*, and warm. In nasal cases he uses carbolic acid in the form of vapor, or in glycerine, or in a one per cent. aqueous solution.

In the second stage he uses stimulants, food, and chloride of iron and quinine; and when the septic stage appears, milk, eggs, concentrated nourishment, whiskey, brandy, wine, etc., in as large quantities as the patient can take, at short intervals. For adults ten drops of the tincture of iron, with half a grain of quinine, every two hours, alternating, night and day, with six or eight grains of chlorate of potash in solution. In the milder cases there may be no need of the high-pressure internal treatment.

Dr. J. E. Winters was in accord with Dr. Billington,

but had found that local treatment in diphtheria, in young children, limited to the throat, was impracticable.

The *first* object of local treatment of throat diphtheria, if the disease was primarily local, was to destroy the cause of the poison, and to do that some strong caustic must be used. Yet everyone who had spoken, except the last gentleman, had opposed this method.

The *second* object was to obtain the benefit of a successful and safe antiphlogistic treatment, which in young children was impossible.

The *third* object was to remove, or absorb, or destroy the membrane, and he did not see why so much importance was attached to this when it was formed only in the upper part of the throat, for if removed or destroyed it rapidly returns. But nature removed it by a catarrhal process beneath the membrane, and that was the only safe way in which to remove it. That which promoted removal of the membrane in this manner was antiphlogistic, and of all measures to be adopted *heat* was the best—heat, externally and internally, faithfully and persistently applied; *hot* applications, and kept constantly hot.

THE PRIMARY INDICATION WAS TO PREVENT THE SPREAD OF DISEASE INTO THE LARYNX, AND HEAT DID THIS.

Implication of the air-passages was accidental, if the case was properly treated from the outset. The patient must be kept absolutely still, and not changed from the recumbent posture *for any purpose whatever*. Then use heat, as far as it can be used, externally and internally. He occasionally used sprays. Steam he had found specially beneficial, and also turpentine, as mentioned by Dr. Jacobi, with internal remedies mentioned by Dr. Billington.

In nasal diphtheria successful local treatment can be carried out if the attendants have sufficient tact. In the *first place*, use something that does not irritate the child in the least, and it will very soon allow thorough treatment so long as it does not produce pain. All this can be done without lifting the child up, and by simply turning it upon its side.

For the swollen glands he could not subscribe to the local external use of ice. In every case in which he had seen it used, he believed it had been injurious. He was afraid of the external use of ice in diphtheria. In septic cases he would use stimulants, when indicated, in large quantities perhaps, and concentrated nourishment.

Dr. H. D. Chapin greatly preferred spray to the syringe in treating the throat, as syringing usually gives rise to the complication of vomiting. He usually has the tongue depressed, and then gives the bulb two or three compressions, when the solution is thrown directly upon the membrane.

Dr. Beverley Robinson was very much opposed to the use of any form of douche in either the throat or nose, because it would produce vomiting. He favored sprays, but the ordinary spray-producer was of no special use. One should be used that gives quite a forcible stream, and the only one which he employed was Lefferts', and he uses it with a *single* bulb, so as to get an intermittent stream. The use of a medicine-dropper he regarded as an illusion and a snare. As to the use of caustics, it was old, and had been abandoned by most distinguished physicians as being an utterly useless method of treatment.

He had read with great interest Dr. Jacobi's views concerning the local use of chlorate of potash and its action on the mucous membrane; but he was of the opinion that cubebs was a more useful remedy than the chlorate of potash. Formerly he believed that it had a specific effect against diphtheria, but that view he had abandoned. He did not believe in any remedy that was said to cure all cases. He also believed that the indications mentioned by Dr. Billington might be carried out as thoroughly as possible and still occasional deaths would occur.

Dr. Andrew H. Smith agreed with the practice set forth in the paper, but disagreed with some of the theories advanced concerning the nature of the disease. He was very glad to hear Dr. Winters say that the membrane did not constitute diphtheria, as he did not believe that diphtheria was a local disease. Local lesions occurred in the throat, so also they occurred in the throat in scarlet fever.

NOR DID HE BELIEVE THAT A MEMBRANE WAS AN ESSENTIAL PART OF DIPHTHERIA.

He believed that diphtheria was a disease which was received into the general system, and that it had a local manifestation in a peculiar inflammation of the throat, almost invariably attended by the production of a false membrane that does not constitute the disease.

Thorough local disinfection, however, does very much toward diminishing the mortality of this disease, and it should be applied thoroughly to the nose as well as the throat.

Fluids injected should be of a density corresponding to the blood, in order to avoid irritation. He preferred a weak solution of the bichloride of mercury, with sufficient common salt to give it the proper density—say ʒ j. to a pint of a solution of 1 to 2,000, 3,000, or 4,000 of the bichloride. He also preferred a soft rubber instrument, made by inserting into a small bulb a nipple like that on the end of a medicine-dropper.

Dr. W. H. Thomson had no doubt that, in the majority of cases of diphtheria, local treatment might be all that was required, and he thought that it should be employed. During his experience of twenty-five years he had had opportunity to observe one case in which could be studied not only the period when the manifestations in the throat began, but the condition of the patient before he was sick, when it was suspected that he would have diphtheria.

One of two bed-fellows had nasal diphtheria. The young men were separated at once. The one who had shown no symptoms was eighteen years of age. He was very carefully watched, and his nostrils and throat were carefully inspected. On the ninth day he was taken with a *severe* rigor and chill. The physician inspected his throat within ten minutes after its occurrence, and nothing except a slight redness was found in either throat or nostrils. Within one hour the posterior wall of the pharynx was intensely injected. The constitutional symptoms were extremely grave from the very commencement. On the next day—not until then—diphtheritic membrane was found upon the posterior pharynx, low down, which developed downward and soon caused intense dysphagia, and on the next day swallowing was impossible.

Local treatment was employed, and constitutional treatment by the rectum, and on the sixth day all the membrane had disappeared. The patient had a good appetite, and his temperature was normal. On the evening of the seventh day he had another chill, albumen was present in large quantity in the urine, and within thirty-six hours he died of cardiac paralysis due to diphtheritic poisoning; the membrane appearing *subsequent* to the onset of most serious constitutional symptoms, and disappearing *before* the development of the condition which terminated the life of the patient.

His own treatment had been based upon the internal administration of the antiseptics that can be taken in the largest doses, and the chlorine class can be taken in larger quantities than any other. He uses bromine locally. He also recommends the persistent use of oxygen gas, which is an admirable antiseptic, especially when there is any tendency to necrotic changes.

Dr. A. L. Loomis thought that Dr. Billington had reached the conclusion that every sensible physician must reach who watches his cases as carefully as the writer of the paper had done. He felt confident that diphtheria, in a certain proportion of cases, occurs primarily as a local disease; but he also believed that, in the great ma-

jority of cases, it was already constitutional when the local manifestations appeared. He had travelled over the ground of mechanical removal of the membrane, the use of caustics and astringents, etc., and had come to a place where cleanliness and disinfection seemed to be the only things to be accomplished locally, and these measures were to be sustained by constitutional remedies. In other words, it was his plan to treat the case rather than the diphtheria.

Dr. Billington said that it would ill become him to make any additional remarks after the very generous and courteous reception that had been given to his paper.

The Section then adjourned.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, March 28, 1887.

Laurence Johnson, M.D., President, in the Chair.

Dr. Matthew D. Mann, of Buffalo, N. Y., read a paper entitled

REMOVAL OF SOLID UTERINE AND OVARIAN TUMORS BY LAPAROTOMY,

in which he gave briefly the histories of *nine* cases. The first three were cases of *solid tumors of the ovary*, which occur only rarely. Mr. Tait had said that they do not occur at all; but in that he was wrong, as a study of the literature of the subject would show.

The remaining cases were those of solid tumors of the uterus. The fifth was especially interesting, because of the occurrence of secondary hemorrhage due to

SLIPPING OF THE SILK LIGATURE FROM THE PEDICLE.

This necessitated the opening of the abdominal wound, securing the bleeding stump with a clamp (Wilson's), cleansing the peritoneal cavity, and again closing the abdominal opening. The patient made a good recovery.

The eighth case was interesting because of the occurrence of

PREGNANCY WITH A LARGE UTERINE FIBRO-CYST.

His general conclusion was that removal of solid tumors was not more dangerous than removal of cysts. The diagnosis was more difficult than that of cysts, but the exploratory incision in many cases was less dangerous than allowing the tumor to remain.

As to the indications for the removal of the solid tumors, there was no doubt with regard to the ovarian, but with reference to the uterine there was some difference of opinion.

To Mr. Keith's indications he would add

TWO NEW INDICATIONS

for consideration, namely: Fibroid tumors of the uterus which are wearing the life of the patient out by the intense suffering which they cause, and possibly another class of cases found in the sloughing intra-uterine fibroids.

He preferred the *external* treatment of the pedicle to the internal, for uterine tumors, but

NOT FOR OVARIAN TUMORS,

even though they be solid. Wilson's clamp had contributed to his success.

Dr. C. C. Lee opened the discussion, and said that on the main points in the paper he thoroughly agreed with its author, and in the matter of diagnosis he had nothing to add. He did not, however, quite agree with Dr. Mann with reference to the indications, and thought that he had given rather too wide latitude for the performance of hysterectomy. In all solid tumors of the uterus, Dr. Lee believed that, in young women and where there was a chance for arresting their growth, the methods recommended for that purpose should be most thoroughly considered,

BEFORE RESORTING TO LAPAROTOMY

for the purpose of removing the tumor itself. To make the exploratory incision, to determine whether or not laparotomy should be performed, was quite another matter from that under discussion.

He had never hesitated to reopen the abdominal cavity in cases of secondary hemorrhage, or the early development of septicæmic symptoms, with the view to ascertaining their cause.

Dr. James B. Hunter agreed with Dr. Mann in nearly all that he had said, and especially with regard to the propriety of

REOPENING THE ABDOMINAL CAVITY

under the circumstances mentioned. As to the treatment of the pedicle of solid uterine tumors, he was strongly in favor of the *external-abdominal method.* He preferred to use the elastic ligature rather than the clamp. He thought that the clamp should be allowed to remain as long as possible, in order to make sure that the attachment of the pedicle would not give way.

In certain cases Hegar's operation of removal of the ovaries and tubes would give excellent results.

Dr. Wylie agreed with Dr. Mann except as to some of the minor details of the operation. There was no doubt in his mind regarding the propriety of reopening the abdominal cavity in cases of hemorrhage. But there was

A PRECAUTION IN CASES IN WHICH HEMORRHAGE MIGHT BE EXPECTED,

which he had used and would recommend—namely, the introduction of a drainage-tube, by which the beginning of the bleeding could be at once determined. This tube must be constantly watched. Dr. Wylie would not drop any pedicle that contained muscular tissue into the abdominal cavity. He does not use the elastic ligature, but a metallic constrictor.

Dr. Mundé was in accord with the main views advanced in Dr. Mann's paper. He preferred to use rubber-tubing rather than the solid-rubber ligature, but preferred to use some form of metallic constrictor to either. In the event of the occurrence of hemorrhage after the operation, the abdominal cavity should be reopened and the source of the bleeding sought for.

As to diagnosis, he regarded it as difficult, and especially between

SOFT UTERINE MYOMATA AND MULTILOCULAR OVARIAN CYST.

He had noticed one feature which had aided him somewhat, and he deemed it worthy of mention; that is, when the tumor is a myomata the abdominal walls are thick, whereas in cases of ovarian cyst, which grows more rapidly, the abdominal walls are thinner.

From his observation of cases operated upon by Billroth, Martin, and others, he had come to believe that the pedicle of solid tumors should not be dropped.

Dr. E. N. Liell mentioned that Dr. H. Marion Sims had removed two solid ovarian tumors within the last year, and the specimens had been presented to the New York Pathological Society. Both patients recovered.

Dr. Mann, in closing the discussion, said that his method, in removing the clamp, had been to first remove the clamp, leaving the needles in place, and then apply an

ELASTIC LIGATURE WHERE THE WIRE HAD BEEN,

and leave it to cut its way through the pedicle.

As to Hegar's operation, he did not wish to condemn it, but he had thought that it was not so good a method of treatment as some others. Doubtless in some cases it was the operation to be preferred.

He accepted Dr. Wylie's suggestion as to the use of a drainage-tube, in cases in which hemorrhage might possibly occur, as an excellent one.

He was well aware that the diagnosis was difficult, but doubted very much whether Dr. Mundé's suggestion regarding the thickness of the abdominal walls would be proved to be of very much value.

On motion by Dr. Douglas, the Society gave to Dr. Mann a vote of thanks for his interesting and instructive paper.

The President announced the death of Dr. Lewis Fisher, which occurred in Florida, March 1, 1887.

The Society then adjourned.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

ANOTHER CASE OF RUPTURED BLADDER—RUPTURE OF THE SMALL INTESTINE—GOUTY PAROTITIS AND GOUTY ORCHITIS—PERFLATION IN THE SURGICAL TREATMENT OF EMPYEMA—SOME INCONSISTENCIES OF MEDICAL JOURNALISM—THE DENTAL HOSPITAL OF LONDON—ANOTHER NEW HOSPITAL—DEATH OF DR. CARRINGTON—CLOTTAGE OF THE URETERS—DERMOID CYST OVER STERNUM—SECONDARY CANCER OF PROSTATE—LARGE GALL-STONES—THE LONDON HOSPITAL.

London, March 12, 1887.

A few weeks since I chronicled two cases of ruptured bladder successfully treated by abdominal section, and the sewing up of the wound in the bladder. I have now to record a similar case, which promises to have as fortunate a termination. Last week a man was admitted into St. Bartholomew's Hospital suffering from great pain, inability to pass his water, and in a marked state of collapse. These symptoms had rapidly followed the receipt on the previous evening of a blow over the hypogastric region—the bladder being full at the time. The patient was seen by Mr. Walsham, who thought the case a suitable one for abdominal section, and operated as soon as possible. The diagnosis, previously made, of "ruptured bladder" was speedily confirmed, a rent an inch and a half in length being found in the wall of that viscus. A large quantity of urine was found in the peritoneal cavity. This ran away freely as soon as the abdomen was opened. All the urine having been removed, the abdominal cavity was thoroughly washed out with a one per cent. solution of boracic acid. The wound in the bladder was closed with sutures, which were passed through the peritoneal and muscular coats only. The abdominal wound was closed and dressed antiseptically. There was little shock, and no sign of peritonitis. It was not found necessary to leave a catheter in the bladder, nor even to introduce one at intervals to evacuate the urine, which the patient was able to void voluntarily without much difficulty every four hours. He is now practically convalescent.

A somewhat similar case, but involving the intestine instead of the bladder, is at present under the care of Mr. Croft at St. Thomas' Hospital. The patient, a man aged thirty-six, was admitted a few days since suffering from acute peritonitis. He had received a severe injury to the abdomen the previous evening, and had suffered severely from pain and vomiting. Notwithstanding this he had walked to the hospital. On admission he was found to have all the symptoms of acute peritonitis. His temperature was 103° F. There was marked dulness in the hypogastric region. Rupture of the bowel being considered probable, the abdomen was opened, when the small intestine was found ruptured. The rent in the intestinal wall extended nearly round the bowel, the latter being, therefore, almost severed. The peritoneum was acutely inflamed, and contained a quantity of fæces. The abdomen was washed out with a solution of boracic acid. The wounded bowel was then brought to the surface and stitched to the parietes in the abdominal wound—an artificial anus being thus formed. The peritonitic symptoms rapidly disappeared and neither pain nor vomiting followed the operation. By the last accounts the patient continues to progress favorably.

At the Medical and Chirurgical Society, on March 8th, the proceedings opened with the reading of a paper by Dr. D'Estrées, of Contrexville, on "Gouty Parotitis and Gouty Orchitis." In the ensuing discussion Dr. Garrod, referring to the rarity of these affections, remarked that he had been able to collect two thousand cases of gout, but not one of these had had parotitis.

Dr. Bernard O'Connor mentioned a case of gout, under his own care, in which swelling of the sublingual glands occurred.

A paper by Dr. Ewart and Mr. Fitzroy Benham was then read, in which the history of a case of empyema in which perflation had been successfully employed was narrated. The patient was a boy, aged ten, who had had enteric fever. When convalescing, symptoms, first of peritonitis, and then of pleurisy, came on. Empyema followed on the left side. As an additional complication signs of pulmonary gangrene declared themselves. Aspiration having given only partial relief, the chest was opened in front at the level of the fifth space in the anterior axillary line, and behind at the level of the ninth space in the scapular line. Further, but not sufficient, relief was afforded, although a quantity of pus came away in addition to that previously removed by aspiration. It was therefore determined to employ perflation. By means of a hand ball bellows air was blown through a ten per cent. solution of carbolic acid, and then introduced into the chest through a piece of india-rubber tubing passed through the upper opening for several inches. This procedure, which Dr. Drewitt subsequently likened very happily to "blowing an egg," was highly successful, and caused the expulsion (through the lower opening) of a mass of fetid pus, a piece of gangrenous lung, and some thick pieces of false membrane. The operation was performed under the spray, and was repeated on two subsequent days. After the eighth day the discharge was only serous. Both wounds closed in the fourth week from the date of perflation.

Sir Dyce Duckworth said he believed the practice of washing out the pleura was a mischievous one, and in this view several subsequent speakers seemed to concur. Mr. Godlee suggested the insufflation of iodoform into the pleural cavity. Mr. Pearce Gould preferred a single large opening into the pleura behind. Dr. Ewart, in replying, agreed as to the value of a large opening. With a double tube, perflation could be performed with only one opening. He had not found, in five cases of left empyema, that any effect on the heart was produced by the perflation.

The inconsistencies of medical journalists are hard to fathom. Not many weeks since, one of our weekly medical journals, which has been very free in condemning the system of unqualified assistants, was "called over the coals" pretty sharply by a contemporary. The journal in question, it seems, while battering away at unqualified assistants in one column, did not disdain to take their money for inserting their advertisements in another column.

Last week Mr. Jonathan Hutchinson wrote in wrath to the *British Medical Journal* to denounce the conduct of the *Illustrated London News* in inserting a very fulsome puff (with portrait) of a gentleman whose name has been removed from the *Medical Register* for unprofessional conduct in relation to his method of practice and the advertising of a secret remedy. This week, however, the former journal inserts, in the place of honor on the front page, the advertisement of a medical rubber who is not, and never has been, a member of the profession, and who is, moreover, at the present moment,

undergoing a sentence of twelve months' hard labor for an indecent assault on his servant. The same advertisement also appears in the *Lancet*, though not in so prominent a position. As both these journals referred to the case at the time, and commented very severely on the newspapers for improperly describing the accused as a "surgeon," they can scarcely be ignorant of his status. Yet they not only insert the advertisement of a work on massage by him, but allow the letters B.C., B.S., to appear after his name, implying that he is a university graduate in surgery, whereas he is not even qualified. After this, it is rather hypercritical to write against quackery, and censure the improper assumption of medical titles by men who are, perhaps, qualified. A gentleman to whom I pointed out the advertisement remarked, "That journal ought to be termed the *British Medical Quack*."

Two days ago the Dental Hospital of London held their twenty-ninth annual meeting, when it was stated that during the past year no fewer than 43,745 cases had been treated. Sir James Paget presided at the dinner held in the evening, and observed that the hospital was, in his opinion, the best of its kind that could be found in Europe, or perhaps in the whole world. It also fulfilled a useful office as a school of dental surgery, and encouraged the study of dental science. Two of the finest scientific monographs in the English language, by John Hunter and Richard Owen, respectively, were due to the study of the teeth. He congratulated the dental profession on being now organized as a legalized distinct body.

Another institution for the treatment of skin diseases has been started under the name of The London Skin Hospital. Out-patients only are to be received at first.

The new hospital is the result of a dispute which occurred last summer at St. John's Hospital for Skin Diseases, in Leicester Square. One member of the staff resigned, and, after some delay, has, in company with two other gentlemen, started a fresh clinic within bowshot of the parent one.

London, March 19, 1887.

In a recent letter I referred to a paper lately read before the Clinical Society of London by Dr. Carrington, of Guy's Hospital. I now have to announce his death, after an illness of only two days. He was a distinguished graduate of the London University, having obtained exhibitions and gold medals at several examinations. Although only thirty-three years of age, he had become the senior assistant physician, and would consequently, on the next vacancy, have become full physician with charge of beds. As a teacher he was a favorite, and had already made a mark in medical literature. Within the last four years Guy's Hospital has lost by death four members of its staff and, curiously enough, all on the medical side, viz., Drs. Fagge, Mahomed, Moxon, and Carrington.

At the meeting of the Medical Society of London on Monday last Mr. Harry Fenwick proposed a new operation, which he termed "clottage of the ureters." He brought it forward as an expedient that might be adopted in cases of profuse and uncontrollable hæmaturia, as from a kidney hopelessly crushed by an accident or affected with advanced carcinoma. The operation was performed by (1) introducing his ureter-aspirator into the bladder, (2) practising suction on the ureter of the damaged kidney so as to draw the blood-clots into the eye of the instrument, and (3) making light pressure with the back of the instrument against the finger in the rectum, thereby nipping the ureter lightly and giving time for the blood-clot to collect in the pelvis of the kidney. Mr. Fenwick narrated a case, that of a man aged fifty-one years, who had right renal carcinoma, in which the method was successfully employed. As there was no autopsy, the changes produced could not be verified.

At the Pathological Society on Tuesday evening Mr. Clutton showed a large dermoid cyst removed from over the sternum of a woman thirty-nine years of age. It was first noticed when she was six weeks old. When she was ten years old it was tapped, but no fluid withdrawn. When she was nineteen it was as large as a hen's egg. It remained stationary for some years, but during the last five years had more than doubled in size. After drawing off some of its contents it was ascertained that there was no hole or depression in the sternum, and the cyst was removed entire. The contents (eleven ounces) were found to consist of epidermis, cholesterine, and fat. The wound healed by first intention. Mr. Clutton's specimen excited much interest, and several members related somewhat similar cases. Mr. Stephen Paget remarked that in men with hairy chests there was generally a regular parting at the angle of Ludovic, the hair above growing upward and that below downward. This might indicate some developmental peculiarity of the dermoid structures at this point. The president referred to a case in which there was also a spina bifida. Mr. Clutton, in replying, observed that dermoid cysts might occur in any part of the body, but were most commonly found in the middle line or along lateral fissures.

Mr. Fenwick exhibited a specimen of secondary carcinoma of prostate. He had, he said, been able to find only four cases of the kind recorded. In three of these the primary growth was in the stomach and in the dura mater in the remaining one. In his own case the post-mortem examination showed that the lung was primarily affected, and the liver, spleen, kidneys, prostate, and spinal cord secondarily.

Dr. Pye Smith showed a large gall-stone passed by a lady aged seventy-eight. She had never had jaundice, but suffered from increasing constipation, ending in obstruction. Rectal examination revealed an obstruction above the sigmoid flexure which was suspected to be cancerous. After thirteen days' obstruction the patient passed the gall-stone shown, and the symptoms disappeared. A second larger stone was also shown. It had been passed by a woman of sixty in whom constipation never culminated in complete obstruction.

The London Hospital is the largest in the kingdom, comprising as it does accommodation for some eight hundred patients. Its out-patients are practically innumerable; so much so, that it has within the last few years been found necessary to devise methods for limiting the number and drafting off elsewhere those found to be unsuitable for hospital treatment, being either trivial cases or patients able to pay something. Several other hospitals are contemplating the adoption of similar methods to restrict the numbers of out-patients. Although presenting such a wide field for clinical study, the London Hospital, however, is by no means the largest school of medicine in London. This pre-eminence is enjoyed by St. Bartholomew's Hospital, which, however, in its turn, is far outstripped by the University of Edinburgh. The (comparatively) moderate success of the London Hospital as a school of medicine is doubtless in large measure due to its position. It is located at the East End in the centre of a populous but extremely unfashionable district, viz., in the Whitechapel Road, where its long line of frontage forms quite a feature. Its staff have never been deficient either in learning, zeal, or teaching power, but the success of the school, although considerable, has never been commensurate with the growth of the hospital. The West End hospitals draw an increasing number of students, who prefer the west to the east as a residential district. Considerably more than one-half of the staff of "The London" live west, although this involves a journey of forty minutes to get to their clinique. The position of the London Hospital, both as a hospital and as a school of medicine, is at present gravely imperilled by some recent disturbances which have taken place there. Great dissatisfaction has been expressed among the students by the way in which "outside students," who have commenced their studies elsewhere (in many cases at the University of Cambridge) and only come to the hospital for clinical work, have been promoted to important residential appointments in the hospital over the heads of "London"

students who have entered for the full course. This appears to be the head and front of the offending on the part of the hospital authorities, and the students feel so strongly on the matter that I understand a printed statement has been circulated by them, though I have not seen it. It is rumored that three students were about to be rusticated for the part they took in a correspondence arising out of the above matters, but wiser councils prevailed and, the students showing themselves to be firm in their position and united among themselves, it has been agreed that their statements shall be listened to and, if possible, all grievances removed.

EPIDEMICS OF PNEUMONIA IN THE COUNTRY.

To the Editor of The Medical Record.

Sir: Your editorial, March 5, 1887, calls to mind a singular experience of my own.

In September, 1884, I treated a family living far out in the hills of Northern California. The household numbered twelve—father, mother, and ten children. Within less time than a month ten of the family were sick. Six of the number escaped with bronchitis and pulmonary congestion of different degrees of severity, while four of them suffered with acute lobar pneumonitis.

These four were attacked within a few days of each other. In three of them the lower lobe of the right lung alone was affected; in the fourth the inflammation extended to the lower lobes of both lungs.

I was never able satisfactorily to account for this epidemic (?) of pneumonia. The home was forty miles from the sea-coast, at an elevation of about twelve hundred feet. It was located on the southern slope, was free from fogs, warm and dry.

The sickness occurred at a season of the year when, owing to the excessive dryness of the soil and atmosphere, very little decomposition or putrefactive changes are taking place. The sanitary conditions about the premises were as effectual as they had ever been before, or have since been. I found one defective, obstructed sewer near the house, where the waste waters from the kitchen and wash-rooms were allowed to stand and become impure. This I had rectified. The family has since enjoyed uninterrupted health.

D. P. Hogshead, A.M., M.D.

West Berkeley, Cal., March 12, 1887.

SHOULD DOCTORS FURNISH MEDICINE?

To the Editor of The Medical Record.

Sir: Why should not the physicians of cities give medicine to patients themselves, instead of simply prescribing it?

I have no wish to cast reflection upon the druggists of the country, but how often are complaints made against druggists, for various reasons. How many druggists prescribe over the counter simply for the profits they make from the drugs, keeping money out of the pockets of the already poorly paid physicians, and really casting reflection upon them. For if the remedy happens to do good in a particular case, the family say, "Oh, he's as good as a doctor!" and the conclusion naturally follows that it's no great thing to be a doctor after all.

Then, again, it seems to be the fact that every drug-store is carried on in the interest of some one physician. Who has not met with some instance such as I have lately been a victim of—having a druggist tell a patient that the telephone is out of order and that he (the patient) had better get Dr. So-and-so, who is as good, if not a better, physician than Dr. M.?

I am not writing this letter for spite; but when one sees men getting rich upon the profits which legitimately belong to the physicians, when one notices the numberless small methods which are resorted to by druggists with whom one is not an especial favorite, and when one considers the army of physicians who are barely able to make a living, one wonders why physicians do not prepare and sell the remedies which they consider the patients need.

I do not do it myself, but I cannot see anything wrong about it; nothing unprofessional. Indeed, I believe it would be a good thing for the patients if doctors would prepare the remedies, because thereby many a doctor would get a familiarity with drugs which perhaps was sadly needed.

James McManus, M.D.

Brooklyn, March 19, 1887.

THE DOCTOR'S HORSE.

To the Editor of The Medical Record.

Sir: Your comments on the "Doctor's Horse," in a late issue of The Record, while very good and containing much of interest, cover hardly sufficient ground to constitute a safe guide to a young doctor who really needs experienced advice regarding this very necessary adjunct to the country doctor's armamentarium. Will you allow a word on this matter from one who is somewhat in the position of the rustic member of a nameless legislature. He had sat through a whole session without ever showing any interest in the deliberations of that body, nor having ever opened his mouth in debate; who, when a bill regarding swine was under discussion, at once became attentive, then very restless, and at last could contain himself no longer, jumped to his feet, and cried: "Mr. Speaker, you are talking about hogs; I know something about them air critturs; I was raised among um."

Having practised more or less successfully in a Western State, emigrating from New England twelve years since, and always in a country district where a good horse, in the eyes of the public, is a better recommendation to favor than a diploma and a hospital course, may I add a few "don'ts" to yours for the aid of the young doctor, who, of course, is the one who needs them.

1. Don't buy a horse till you have an office and a fair library, and can buy for cash; and then, only when you need one.

2. Don't buy a young horse, with the prevalent idea it will improve on your hands.

3. Don't buy a horse so old he can't eat; nor an odd-colored horse; nor a small horse; nor a very large horse (bay, sorrel, and brown are standard colors).

4. Don't buy a horse that has been abused, driven hard, underfed when a colt, or anything but a sound horse from six to ten years, with a Morgan strain, if possible. Soundness, gentleness, and endurance are better than speed and beauty.

5. Don't drive for "show." You will be found out if you do. Nor drive fast around town or elsewhere, unless necessary.

6. Don't draw a four-wheeled covered carriage in the country with one horse.

7. Don't swop horses and be known as a jockey.

8. Don't think more of your horse than you do of your patient, nor so much of your patient that you will kill your horse.

9. Don't care for your own horse if you can hire help; or, if you can't afford help, don't visit your patient with the clothes you harness, etc., in.

10. Don't talk *horse* to everybody, nor to anybody unless they begin it.

11. Don't buy a horse till you've tried him thoroughly.

12. Don't buy a *horse* at all; buy a mare, for various reasons not necessary here to mention.

Country Doctor.

New Instruments.

DOUBLE-CURRENT NOZZLE FOR URETHRAL IRRIGATION.

By LOUIS F. KIEFER, M.D.,

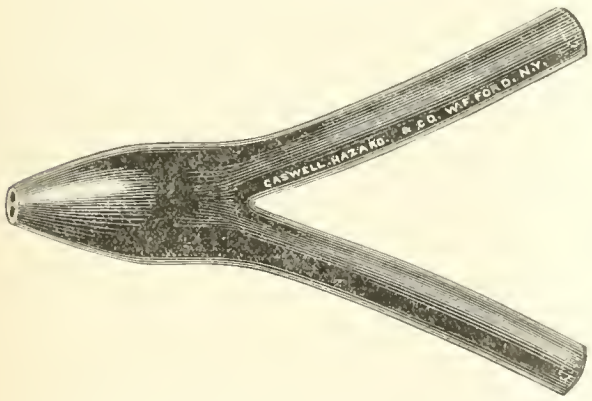
NEW YORK.

While working in the Genito-Urinary Clinic of the Roosevelt Hospital, of this city, I often found great difficulty in thoroughly irrigating the urethra (in that treatment of gonorrhœa) with the nozzles in use; sometimes almost failing to attain that object.

The bulbous nozzle, connected to but one tube, would fulfil the indication of occluding the meatus urinarius, but when the urethra was distended with the fluid it was necessary to partially remove the bulb in order to allow the fluid to escape, and if the patient was at all restless the bulb would slip away from the meatus, and it would then have to be reapplied, a process consuming time and patience; and if the meatus was very small, or the glans penis very slippery, there was often found great difficulty in keeping the bulb applied to the urethral orifice.

We then tried the ordinary straight glass tube with a smooth point; this was introduced a very short distance into the meatus, the urethra was filled with the fluid, and the tube then withdrawn; but these repeated introductions would often cause pain, it would be necessary to have several sizes of nozzles, and if, as was often found to be the case, there was a stricture very close to the meatus, irrigation with this nozzle was often found to be attended with great pain and difficulty.

It then occurred to me that these objections could be overcome by a nozzle which was bulbous, but which was provided with a tube for a return current; such an instrument I have found to fulfil all the requirements of a nozzle for this plan of treatment of gonorrhœa.



The instrument is made of hard rubber (glass having been found to be too brittle), and is about three inches in length. It consists of two tubes, one end of each being free, the other ends being united side by side in a bulbous expansion; the bore of each tube, however, remains separate, and each tube opens separately at the apex of the bulbous extremity. The bore and orifice of one tube is smaller than that of the other; the smaller will be designated the *inflow*- and the larger the *outflow*-tube.

The inflow-tube is intended to be connected to the tubing from a fountain placed at a proper elevation. The conical bulbous end is so made in order to fit the varying sizes of urethral orifices, and when once inserted into the meatus can be firmly held there without interfering with the outflow of the fluid.

The instrument is intended to be used as follows: The inflow-tube having been connected to the tubing, as stated above, and the fountain filled with the desired solution, the conical bulbous end is to be inserted into the meatus and firmly held there by one hand; the solution may now be allowed to flow through the inflow-tube, and if now the free end of the outflow-tube be closed by a finger of the disengaged hand, the medicated solution will then distend the urethra, and thus come into contact with every portion of the urethral walls. This manœuvre can be gone through with from fifteen to twenty-five times a minute, thus making it possible to thoroughly irrigate the urethra with a quart or more of medicated solution in a very short time.

The bore of the outflow-tube was made the larger in order that the urethra would be thoroughly and promptly emptied, and thus a constantly renewed application of the irrigating fluid to the urethral walls be insured.

If a cold solution is used, the danger of the fluid entering the bladder is very slight, the local effect of the cold solution being to cause a tonic contraction of the sphincter vesicæ; the fountain, however, should not be placed too high—about three feet above the level of the nozzle when in use has been found sufficient. The instrument, being made of hard rubber, can be kept in antiseptic solutions without injury, an advantageous feature which is self-evident.

To avoid using the finger to occlude the outflow-tube, I have devised an arrangement of levers so placed that when the outflow-tube is occluded the inflow-tube will be open, and *vice versa;* this, of course, is merely a refinement.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 27 to April 2, 1887.

Perley, Harry O., Captain and Assistant Surgeon. Ordered for temporary duty at Fort Maginnis, Mon. Ter. S. O. 23, Department of the Dakota, March 18, 1887.

Official List of Changes in the Medical Corps of the United States Navy for the week ending April 2, 1887.

Waggener, J. R., Passed Assistant Surgeon. Commissioned a Surgeon on March 18th.

Fitts, H. B., Passed Assistant Surgeon. Ordered to the Receiving-ship Vermont.

Tracy, E. C., Assistant Surgeon. Detached from the Vermont, and ordered to the Atlanta.

Heffinger, A. C., Passed Assistant Surgeon. Detached from the Atlanta, and ordered on special duty in connection with construction of a hospital at Widow's Island, Me.

Hager's Catarrh Remedy.—The formula recommended by Dr. Herman Hager is as follows: Of carbolic acid, 10 parts; alcohol, 10 parts; water of ammonia, 12 parts; distilled water, 20 parts. Take two-ounce wide-mouthed bottles, fill them to one-third with the above liquid; then introduce a bunch of (absorbent) cotton of sufficient size to soak up all the liquid; to be used in incipient cold in the head, coryza, chronic catarrh, etc. A stronger preparation, also recommended by Dr. Hager, is the following: Carbolic acid, 10 parts; oil of turpentine, 5 parts; water of ammonia, 12 parts; alcohol, 20 parts. To be used in the same manner as the preceding. Hager recommends those as prophylactics against diphtheria. He advises all those who handle and are about patients suffering from diphtheria or phthisis, to place a vial with this *olfactorium* to the nose when they approach the patient.—*Therapeutic Gazette.*

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 2, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	11	5
Scarlet fever	67	10
Cerebro-spinal meningitis	4	3
Measles	122	15
Diphtheria	84	40
Small-pox	8	2
Yellow fever	0	0

CEREBRAL ABSCESS AND ITS TREATMENT.—A discussion on the diagnosis and treatment of cerebral abscess took place at the Glasgow Medico-Chirurgical Society on February 11th and 12th, but does not appear to have added much to current knowledge. Dr. William Macewen mentioned a case of abscess in the temporo-sphenoidal lobe upon which he had operated with success. Mr. Barker, who had another successful case (with Dr. Gowers) about three months ago, is reported to have stated that nearly all intracranial abscesses originating in ear-disease were in the cerebrum, and that nine-tenths of the cerebral abscesses were in the temporo-sphenoidal lobe. Such abscesses, though not very commonly met with, are not extremely rare; for instance, Professor Greenfield said he met with about one case a year in the Edinburgh Infirmary, and Dr. Coats said that the number in Glasgow was proportionate, so that probably this operation, which appears to present no serious difficulties to the surgeon, will soon become comparatively frequent—more especially as the first five cases (treated by Barker and Gowers, Schondorff, Trückenbrod, Greenfield, and Macewen) have been so successful. Altogether, there seem to have been twenty cases recently in which the cerebrum has been incised or partially excised, with three deaths, two from shock and one from septicæmia.—Cor. *Phila. Med. Times.*

BILE-SALTS AND COD-LIVER OIL INUNCTIONS.—Dr. H. A. Hare, of Philadelphia, finds that the addition of bile-salts doubles the rapidity with which cod-liver oil can be rubbed into the skin.—*Boston Med. and Surg. Jour.*

A CURE FOR WARTS.—Take fifteen grains of corrosive sublimate and dissolve in one ounce of collodion. Brush the warts carefully once a day with this solution. This remedy is more efficacious and more convenient than other recommended procedures.—*Zeitschrift d. Oester. Apotheker-V.*

ANTISEPTIC COLLODION.—The *Journal de Médecine* of December 26th contains an account of a new kind of "collodion," which is antiseptic and promotes cicatrization. It does not cause inflammation, and may be substituted for collodion made from gun-cotton, in the treatment of wounds and bruises. Like traumaticine, it is efficacious in relieving neuralgic pains and acute or chronic rheumatism. The affected parts should be sponged with it every twenty-four hours, and in serious cases every six hours. If strips of linen or silk be soaked in this collodion, an excellent sticking-plaster is obtained, which quite equals English court-plaster. The following is the formula: Mastic in globules, 3 grammes; balsam of Peru, 1 gramme; narcotine, 1 gramme. Each ingredient should be ground separately, and 5 grammes of chloroform added thereto.

TREATMENT OF BOILS BY INJECTIONS OF CARBOLIC ACID.—Dr. Bidder, of Paris, has described a method of treating furuncles by parenchymatous injections of carbolic acid. If the boil is a small one, he gives one injection of a few drops of a solution of carbolic acid (two per cent.); if it is of medium size, two injections are given, the half or the whole of a Pravaz-syringeful of the solution being used on each occasion. In the case of large furuncles, for example, half the size of a man's hand, Dr. Bidder injects at four different spots the contents of four Pravaz syringes half or wholly filled with a solution of two per cent. of carbolic acid. These injections are given only once. This treatment is strikingly successful. There is some smarting at the seat of injection at first, but the pain soon disappears, and the next day there is a marked improvement in the patient's condition. The inflammatory swelling subsides very quickly, and in eight or ten days even the largest furuncle is dispersed. By this plan no unsightly scars are left, a circumstance which in many cases is of considerable importance. The success of the treatment is probably to be accounted for by the fact that either the microbes which cause the disease are killed, or the medium in which they flourish is destroyed.—*British Medical Journal.*

AN INGENIOUS TEST FOR VISUAL MALINGERING.—In a large factory a workman in wielding his hammer carelessly allowed it to slip from his hand. It flew half across the room, striking a workman in the left eye. The man brought suit in the courts, and although an eminent oculist, after an examination, declared that no apparent injury could be detected, claimed that his eyesight was destroyed, and refused all offers of compromise. As the law requires owners of factories to pay all claims for damages resulting from injury during work, the owner, though confident that the man was shamming, had about made up his mind that he would be compelled to pay the claim. On the day of the trial a further test was made. The oculist for the defence had a pair of glasses made, the right eye being of red and the left eye of ordinary glass. He brought also a black card with a sentence written on it in green ink. The plaintiff was ordered to put on the glasses and read the sentence, which he readily did, thus proving himself a perjurer, as the sound right eye, being fitted with a red glass, could not distinguish the writing—the combination of green and red producing black, which on a black ground was, of course, not visible—and the left eye, which he claimed was blind, was the one with which the reading had to be done.

LOVE IN CAPSULES.—A Kentucky medical contemporary publishes a love-song in its pharmaceutical department.

A HORN GROWING FROM THE HUMAN HEAD.—An interesting addition has just been made to the museum of the Hôpital Saint Louis, in Paris, in the shape of a strong and solid horn, which has been surgically removed from the head of a woman residing at Hyères, in the Riviera. This appendage grew from the scalp, was twenty-one centimetres (eight inches) long, and in appearance and consistence resembles the horn of a goat. This deformity is rare, but not so much so as is generally imagined. Cloquet, the eminent anatomist, records a case, and Demarquay has collected fifty-nine cases. The late Sir Erasmus Wilson gives a very complete account of the deformity in the twenty-seventh volume of the "Transactions of the Royal Medical and Chirurgical Society." Out of 90 cases mentioned therein, 44 were in females, 39 in males, and the sex of 7 is unrecorded. In the *New York Medical Repository* of 1820 is described the case of a man from whose forehead grew a horn which had three branches and was fourteen inches in circumference. These growths have their origin in a diseased sebaceous gland, and their treatment is removal. It is necessary to destroy all remains of the offending sebaceous gland, or recurrence may happen.

A CASE OF ACUTE AND FATAL TUBERCULOSIS OF THE LYMPHATIC GLANDS.

BY FRANCIS DELAFIELD, M.D.,

NEW YORK.

HELEN R——, aged twenty-three, England, domestic, was admitted to St. Luke's Hospital, under the care of Dr. A. B. Ball, on October 18, 1886. She had been in good health until two weeks before her admission to the hospital. At that time she was attacked with headache, pain in the back, malaise, diarrhœa, occasional vomiting, and a febrile movement. For the first week she continued up and about, during the second week she was in bed. It was supposed that she had typhoid fever.

When admitted to St. Luke's Hospital her temperature was 99° F., pulse 84, respiration 23. The urine contained no albumen, sugar, or casts. There was no diarrhœa. The spleen was slightly enlarged, the liver was of normal size. There were no physical signs of disease of the heart or lungs, except a few coarse râles over the lower part of both lungs. The patient's appearance was cheerful, and so unlike that of typhoid fever that in the absence of characteristic symptoms the disease was excluded from the diagnosis.

The only change for the next four days was a gradual rise of temperature from 99° to 102° F.

On October 22d, for the first time, it was noticed that there was an enlarged lymphatic gland on the right side of the neck near the angle of the jaw. This gland was somewhat larger than a hickory nut, hard, tender, and freely movable. She said that it had appeared at the outset of her illness, and since then had become larger. No cause for this enlarged gland could be discovered in a primary lesion elsewhere. The axillary and inguinal glands were not enlarged. After this time the temperature ranged from 102° to 104° F. The enlargement of the glands in the neck became more marked, and extended down to the clavicle.

There were no physical or rational signs of disease of the lungs.

The patient lost flesh and strength, and became anæmic. The red blood-cells were 3,720,000 to the cubic centimetre, the white blood-cells were in the proportion of 1.832, the hæmoglobin was forty-eight per cent.

By December 4th an enlarged gland had appeared in the right axilla, and the glands in both groins had begun to enlarge.

On December 5th the eyes were examined by Dr. Loring. In the right eye the arterial and venous blood was lighter colored than usual, the veins were dilated. Above and to the outer side of the macula was a small hemorrhagic spot, surrounded by œdema, and several spots of exudation in the retina. At another part of the retina was a white spot, as large as a pin's-head, with a foggy appearance; and near this the retina had a striped, granular, pepper-and-salt look. All the changes were in the neighborhood of vessels, and somewhat resembled the retinitis of leukæmia, or Bright's disease.

The left eye was in much the same condition as the right.

On December 7th a sharp diarrhœa set in, with a fall of temperature nearer to the normal. The patient became extremely prostrated, looked as if she would die, and was removed from the hospital by her friends. On January 8, 1887, Dr. Ball saw the patient at her home, in consultation with her physician, Dr. S. M. Swift. Since she had left the hospital there had been a constant elevation of temperature, but with lower ranges. Her general condition had somewhat improved.

While the patient was under the care of Dr. Ball, at St. Luke's Hospital, she was seen by all the consulting and attending staff, and the results of their study of the case are stated by Dr. Ball as follows:

"After the first few days it was evident that she was suffering from an infective process of some kind. Typhoid fever was early excluded. When the swollen and tender gland at the angle of the jaw was discovered it became a question whether such a prolonged and marked constitutional disturbance could arise from a simple adenitis, inasmuch as no other lesion could be detected. She was seen by three of the surgical staff, two of whom thought the symptoms might be accounted for by adenitis, while the third doubted this possibility, but had no other explanation to offer. This difference of opinion is mentioned simply to show the difficulties which attended the diagnosis from the start. A few days later the continued high temperature, and the evident though inconsiderable enlargement of the spleen, led to the suspicion of a general tubercular infection; but although careful examinations were made repeatedly for signs of its existence, no satisfactory evidence was obtained. When, five weeks after admission, the lower cervical and supra-clavicular glands began to enlarge, it became a question whether we were dealing with a tuberculosis limited, for the most part or entirely, to the glandular system, or with an acute form of Hodgkin's disease. At this time the physical signs at the apices of the lungs were but slightly marked, and could be explained, it seemed to me, by enlargement of the bronchial glands. My reasons for this opinion were that the patient was entirely free from cough, there was no evidence of a general tuberculous infiltration of the lungs, and the fact that the local signs had not made their appearance until after infection of the lower cervical and supra-clavicular glands had taken place, with a probable extension of the process to the bronchial glands. Assuming the correctness of the supposition that the morbid process was limited to the glandular system, the chances were in favor of a lymphomatous or lympho-sarcomatous affection rather than a tuberculosis, on account of the greater rarity of a tuberculosis thus limited. To be sure, Hodgkin's disease seldom runs its course with such rapidity and such continued high temperature, but a considerable number of cases so characterized have been reported by Gowers, Hilton-Fagge, and other writers. Splenic enlargement occurs in both diseases, and has no value for the purpose of differential diagnosis between them. In reviewing the case it seems to me highly probable that infection of the spleen, and perhaps of the deep abdominal glands, took place very early, and were really the cause of the fever which ushered in the illness. Indeed, I am not sure that the disease did not start in this locality rather than in the cervical gland, which seemed to us the primary focus.

"In cases presenting similar difficulties of diagnosis the nature of the disease may be cleared up by a simple procedure suggested to me in the present case by Dr. Abbe—viz., to remove a portion or the whole of an infected gland and examine for tubercle bacilli. The suggestion

was not carried out with my patient on account of the serious character of her illness and my reluctance to add to her discomfort without some likelihood that the information obtained could be utilized in the treatment."

On January 24, 1887, the patient was admitted to the Roosevelt Hospital under my care. She was feeble and anæmic, her eyesight was poor, her tongue was clean and moist, her appetite was poor, there was constant pain in the abdomen, and the bowels were loose. The urine was acid; specific gravity, 1.024; a trace of albumen, no sugar, no casts. Temperature, 101.8° to 103.4°; pulse, 120 to 130; respiration, 32 to 36.

Over the lungs the percussion note was normal; there was tubular breathing over both lungs, such as is usually due to compression or narrowing of the trachea or large bronchi. The heart was normal, except for a systolic murmur in the second left interspace. The liver and spleen were of normal size, and no tumor could be felt in the abdomen.

In the right side of the neck, extending from the angle of the jaw to below the clavicle, was a mass of lymphatic glands—hard, matted together, and adherent to the surrounding parts. There were a few glands, very slightly swollen, in the right axilla and groin. After her admission the patient's temperature was between 103° and 104°, with a regular afternoon rise. The pulse was from 120 to 130, and the respirations from 30 to 40.

She lay quietly in bed in a somewhat apathetic condition, from day to day looking rather worse and more emaciated, then became mildly delirious, and on February 7th, at 4.50 A.M., died rather suddenly, having looked on February 6th as if she would still live for some time.

I made the autopsy on February 7th, at 2.40 P.M.

The brain and its membranes were normal, except for some increase of serum in the lateral ventricles.

The lungs were congested and œdematous. In both lower lobes were considerable areas of red hepatization and a very few miliary tubercles.

In the areas of red hepatization the air-spaces contained pus, fibrine, red blood-cells, and epithelial cells. The miliary tubercles were composed of infiltrations of round cells.

The heart was normal.

The liver weighed five pounds, contained but little blood, and the hepatic cells were largely infiltrated with fat.

The spleen was slightly enlarged, and contained a large number of white nodules from the size of a pin's-head to that of a pea. The nodules had for the most part undergone cheesy degeneration, and showed no structure except a few round cells at their peripheries. They contained tubercle bacilli.

The stomach was empty; its glandular coat was well preserved and normal.

The pancreas was unchanged.

The small intestine and the colon were normal.

The mesenteric glands were much enlarged. Some of them were calcified, others had undergone cheesy degeneration and softening. In none of them was there any well-marked tubercle tissue, as the degenerative changes were extensive, but tubercle bacilli were found in the cheesy masses.

The kidneys were a little enlarged. The epithelial cells of the convoluted tubes were slightly swollen.

The thoracic duct was unchanged. In the right side of the neck was a large mass of lymphatic glands, extending from the angle of the jaw downward below the clavicle, and inward toward the trachea. Most of these enlarged glands had undergone cheesy degeneration at their centres, and some had softened. There was no well-marked tubercle tissue, but tubercle bacilli were present in considerable numbers.

The patient, apparently, had suffered at some former period from an attack of tubercular inflammation of the mesenteric glands, from which she recovered, the glands undergoing calcification. If any ulcers existed in the small intestine at that time, they left no cicatrices behind.

Her present illness began with a tubercular inflammation of the mesenteric glands, again without ulcers in the intestines. After a time the cervical glands became inflamed in the same way, and a few miliary tubercles were formed in the lungs. From the beginning to the end of this fatal illness the patient always looked as if she were suffering from the poison of some general disease, and not from interference with the functions of any part of the body; and after death none of the viscera were so altered as to render life in danger, nor were the anæmia or the emaciation so marked as to account for death.

The case seemed to be a well-marked example of tubercular inflammation of the mesenteric and cervical glands, which behaved like a general rather than like a localized tuberculosis.

Tubercular adenitis, involving by preference the cervical, bronchial, and mesenteric glands, is usually a secondary inflammation to lesions of the skin, lungs, and intestines. It behaves like a localized tubercular inflammation, but occasionally becomes the starting-point of a general tuberculosis.

Tubercular adenitis of a primary character, and behaving like a general tuberculosis, is much less common.

Some cases of this kind are described by the older authors under the name of acute scrofula.

Others have been confounded with the morbid condition known under the names of Hodgkin's disease, pseudo-leukæmia, adenia, anæmia lymphatica, lymphadenoma, malignant lymphoma.

A few cases similar to the one here reported have been described by Dr. Hilton-Fagge[1] and Dr. Pye-Smith.[2]

ANTIFEBRIN IN THE TREATMENT OF PHTHISIS.

By CHARLES M. CAULDWELL, M.D.,

VISITING PHYSICIAN TO ST. JOSEPH'S HOSPITAL, NEW YORK.

Ever since Cahn and Hepp introduced antifebrin to the notice of the medical world, the drug has been rapidly gaining favor in the eyes of German, English, and American observers. Almost every week the European medical journals publish the commendatory opinions of one or more practical investigators. In many of the New York hospitals antifebrin is already accepted as the safest and most reliable drug with which to reduce temperature in *acute* febrile diseases.

Thus, while both hospital and private practice furnish abundant evidence of its power in such diseases as typhoid fever, pneumonia, and acute rheumatism, yet the fact that it is capable of producing most desirable results in certain forms of phthisis does not seem to be appreciated.

Last fall I was surprised to see moderate doses of antifebrin quickly control a most distressing "hectic fever," after quinine, antipyrine, etc., had completely failed. Since that time I have employed the drug in the treatment of thirty phthisical patients, in whom persistent fever, or chills and fever have been prominent symptoms. The results have been unexpectedly satisfactory both to me and to the patients.

The cases for which the drug was prescribed differed widely in age, habits, and social position, some being private patients while others were hospital inmates. The sexes were about equally represented. Of the thirty patients, nine were suffering from slight or moderate consolidation in *one* lung only. Eleven had more extensive disease, namely, considerable patches of consolidation, with or without spots of softening. The ten remaining cases were pitiable examples of the cavernous stage of phthisis.

[1] Path. Trans., xxv., 72 and 235.

[2] Ibid., xxvi., 202.

In cases of the first class (those having moderate consolidation in one lung only) antifebrin immediately produced marked improvement. The temperature became normal, the pulse was less rapid and stronger, the tongue cleared, the appetite improved notably, dyspeptic symptoms disappeared, "chest pains" and nervous sensations ceased to annoy, the secretion of the urine increased, and the patient acted and appeared greatly benefited.

The following outline will fairly illustrate the effect of the remedy upon the temperature, etc.; also the dose given in cases of the first class.

Case V. was a young lady, twenty years of age, who had had phthisical symptoms for eight months. At the time of coming under observation there was a moderate amount of consolidation at the apex of the right lung. The patient had been abroad in search of health for six months, but had returned unimproved. During the month which preceded the antifebrin treatment her prominent symptoms were daily fever, dyspepsia, and night-sweats. The girl was thin, anæmic, and each afternoon had a brilliant hectic flush, especially upon the right cheek. The day before the drug was commenced the record stood as follows: At 8 A.M., temperature 101¼°, pulse 104; 1 P.M., temperature 103°, pulse 122; 8 P.M., temperature 101¾°, pulse 110. A single dose of castor-oil was given. Then seven grains of antifebrin, four times a day, was prescribed. Each dose was taken in an ounce of champagne shortly after eating. This treatment was continued for two weeks, at the end of which time the patient was sent South. During these two weeks the girl's temperature remained below 100°, pulse below 90. The symptoms of indigestion subsided, appetite returned, and there was an increase of five pounds in bodily weight. This was more than had been gained during her whole European trip.

In cases of the second class, including those whose disease had advanced sufficiently to produce either extensive consolidation or spots of softening, antifebrin kept the temperature normal, slowed the pulse, improved digestion and appetite, and diminished restlessness and insomnia. In several of these cases free sweating was produced when this occurred; it was obviated by the addition of agaricin to the treatment. In two cases blueness of the lips and finger-nails was noticed. This was doubtless due to the antifebrin. The cyanosis was unaccompanied by any discomfort, both patients declaring that they felt "all right" at the time and afterward.

The following notes will give a correct idea of the doses given and the amount of relief obtained from the remedy in this second class of cases, also the symptoms which the drug did *not* influence favorably.

Case XVII. was a young man, aged twenty-three, who had been losing flesh and strength for five months. He had had severe cough and occasional small hemorrhages for three months before I saw him. At the time of coming under observation there was a point of softening in the upper part of the left lung. Hectic fever, night-sweats, loss of appetite, racking cough, and dyspnœa were the troublesome symptoms. The temperature was taken for a week, and found to reach 103° and over in the afternoons. Antifebrin was ordered—ten grains at 8 A.M. and at 4 P.M.—to be taken in a little whiskey and ginger-ale. An hour before bedtime a pill of agaricin (gr. ⅙) was given to prevent "sleep-sweating." The following is part of the temperature record:

December 14, A.M., 102¼°; P.M., 103¾°. Night-sweat. Antifebrin commenced.
December 15, A.M., 102½°; P.M., 102°. Night-sweat.
December 16, A.M., 100°; P.M., 98¾°. None.
December 17, A.M., 98½°; P.M., 98⅘°. None.
December 18, A.M., 98⅘°; P.M., 98⅗°. None.
December 19, A.M., 99°; P.M., 99⅕°. None.
December 20, A.M., 98½°; P.M., 98⅘. None.

The treatment was continued for three weeks. During that time the fever and sweating were entirely controlled. Appetite returned, but neither cough nor dyspnœa were modified, although the young man improved in flesh and strength.

The third class of cases in which antifebrin was tried consisted of patients in whom both lungs were extensively diseased, and from whose general condition it was only too evident that they were soon to journey to "that far country from whose bourne no traveller returns."

Even in such advanced cases the drug afforded much comfort by controlling the septic chills and fever, and quieting the restlessness. In no case did the remedy fail to check the distressing chills at once.

The following case will illustrate this point:

Case XXVIII. was a man, twenty-nine years of age, who had been ill with consumption for a year and a half. On admission to the hospital he had advanced diseases in both lungs, was bed-ridden and emaciated to an extreme degree. Each morning at about ten o'clock he had a chill sufficiently severe to shake the bed and cause his teeth to chatter most vigorously. Each chill was followed by fever and a drenching sweat. Anorexia, constant thirst, severe cough, dyspnœa, chest pains, attacks of syncope, and mild delirium added to his distressing condition.

Capsules containing ten grains of antifebrin and one-fifth of a grain of agaricin were ordered to be taken daily, at 9 A.M. and 9 P.M. A little aromatic spirits of ammonia was used as the accompanying stimulant. After the first day the chills never returned; the temperature remained below 100°, the sweating was less profuse, the mind became clear, and the extreme restlessness disappeared. The treatment was continued for two months, during which time it produced no unpleasant effects, and greatly modified the poor fellow's sufferings.

In regard to the doses used I believe mine were a little larger than are generally prescribed. From twenty to thirty grains were given in twenty-four hours. After the chills and fever had been controlled for a few days, the doses were reduced one-half, and continued for a variable time before entirely suspending treatment.

It was the rule in all cases to give some form of stimulant with each dose of antifebrin, in order to obviate any depression which might possibly be produced. It is very doubtful if this is necessary, however.

The drug is apparently an antiseptic. Lépine thinks that its action is due to aniline, which, being set free from the antifebrin, exerts its antiseptic power.

My experience with the drug in the treatment of consumption leads me to the following conclusions:

1. Antifebrin is the best drug with which to control the chill and fever of phthisis. With it we can at once check these depressing symptoms.
2. It does not produce the unpleasant effects of quinine, salicylic acid, antipyrine, thallin, or resorcin.
3. Chills, collapse, or semi-intoxication are not caused by it.
4. In many patients it induces sweating.
5. It diminishes the frequency of the pulse, and usually strengthens the heart's action.
6. Occasionally it produces cyanosis. This happened but twice in thirty cases.
7. It does not interfere with digestion; but, on the contrary, increases the appetite.
8. Even when the stomach is in an irritable condition it can be retained.
9. It increases the secretion of urine in the majority of instances.
10. It tends to quiet the nervous system, and produce a feeling of "well-being" in the patients.

71 West Fifty-fifth Street.

Buffalo Claims a Birth-rate of 31.5 per 1,000 in 1886; Rochester, which is very near, has a rate of 16.66 per 1,000. The Buffalo *Medical and Surgical Journal* says that there is some grave defect either in the vital statistics or in the fecundity of Rochester people.

A CASE OF PROGRESSIVE FACIAL HEMIATROPHY.[1]

By L. PUTZEL, M.D.,

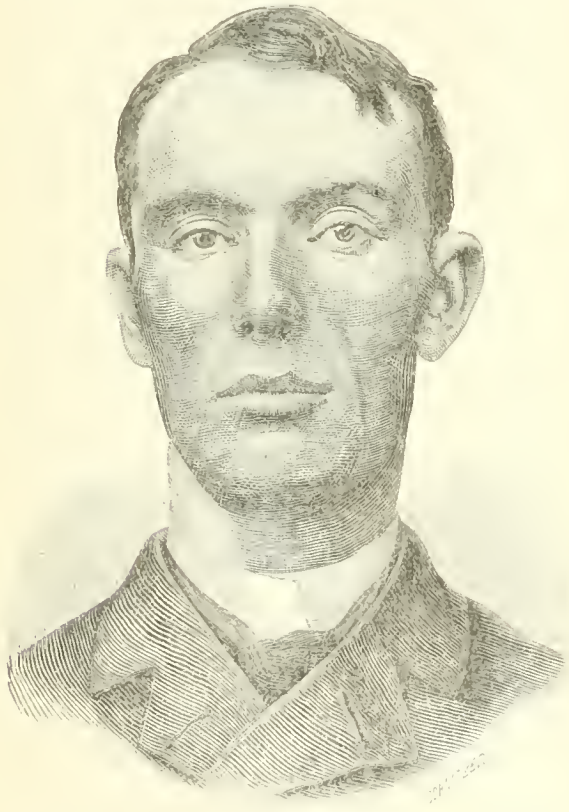
NEW YORK.

The following is the history of the patient who forms the subject of my paper this evening:

Francis F——, aged twenty-seven, was a farm-hand until a few months ago, parents living and healthy, had nine brothers and sisters (six died soon after birth), three living ones are healthy. Father has a nervous disposition; mother suffers from some sort of colic attacks (?) on getting excited; patient's uncles are quick and excitable.

Patient had measles at the age of ten, but otherwise always in good health. Very temperate as regards drink, absolutely continent in his sexual relations.

Five or six years ago he had catarrh of the left side of the nose, which he used to blow with extreme violence in order to dislodge clumps of inspissated mucus. The nasal catarrh has disappeared almost entirely. Five years ago he began to notice a slight depression just below the left eye, and this kept moving slowly downward. He is positive that it was unattended by discoloration of the skin.



Present condition—appearance of the face.—The left eyebrow is considerably higher at the middle of the arch than the right brow. The left eye is somewhat sunken, and looks and feels a little smaller than the right; the finger can be pressed into the left orbit more deeply than into the right. The upper part of the superior maxilla and the anterior processes of the malar bone are considerably depressed, the normal convexity of the right side in this locality being replaced by a concavity. The left nostril is a trifle higher than the right. In repose a deep furrow is observed to run along the left side of the face from the anterior part of the malar bone downward, and outward to about two inches from the chin. There appears to be a slight depression over the left temporal muscle. The integument of the left side of the face, particularly over the malar bone, is thinner than on the right side; folds of skin, when pinched up between the fingers, are decidedly thinner than on the opposite side, and cannot be removed so far from the underlying bones (atrophy of the subcutaneous tissue). On introducing the finger into the mouth, the left masseter is found to be slightly smaller than the right, and does not contract quite so vigorously.

The patient can move the facial muscles of both sides with unusual facility, but on the left side violent contraction of the muscles is attended with the production of three broad, thick transverse folds, running from the inner angle of the eye across the upper part of the nose; these are barely indicated on the right side. The electrical muscular reactions are equal on the two sides, but there is perhaps a slight diminution of the faradic excitability of the left lev. labii sup. alæque nasi.

Sensation is normal, but the patient has noticed a slight feeling of numbness in the depression for the last two years. He has never suffered from pain in the affected region. He states that the cutaneous secretions are alike on the two sides, and no difference is noticeable in the skin.

The tongue and buccal cavity are normal in all respects, and nothing is noticeable about the special senses. According to the patient, the atrophy has been progressing slowly since the inception of the malady.

Remarks.—Progressive facial hemiatrophy is a comparatively rare disease. Probably about seventy cases have been hitherto reported. My own case presents a peculiarity which is worthy of mention. Most of the reported cases began with spots of pigmentation on the affected skin; whitish, brownish, or yellowish patches, and changes in the hairs were observed in quite a considerable proportion. These are absent in my case. A certain number were associated with atrophy of the corresponding side of the palate and tongue. Absence of the sebaceous and sudoriparous secretions has also been noticed, and even oculo-pupillary symptoms have been mentioned. The power of blushing has sometimes been lost on the affected side. As a rule, the special senses have been normal, but in a few cases impairment of hearing and taste has been observed.

Wolff reports a unique case of bilateral progressive facial atrophy. In this case the atrophy developed on the two sides after a long interval. Wolff attributed the atrophy of the right side to scarlatina, followed by chronic tonsillitis, and which, in his opinion, gave rise to a chronic neuritis. The changes on the left side began after typhoid fever, and Wolff is also inclined to attribute these to an infectious neuritis.

Nicaise reports a case of median facial atrophy, affecting the median part of the forehead. It began at the age of twenty, in the third month of pregnancy. It began spontaneously, accompanied by violent headache. The skin was dry and thin, and applied directly to the bone, but not adherent; the hairs were scanty, and had turned white. The muscles were also atrophied.

Henschen reports a case which presents an interesting etiology. The patient, aged forty-six, at the age of fourteen sprained the left ankle. Six months later atrophy began in the left lower and upper limbs and the left side of the trunk, and later extended to the left side of the face. The patient was melancholic for a time at the age of nineteen, and had a relapse of melancholia two years ago, which has now disappeared. The atrophy affected the entire left side of the face (bones, etc.). The left side of the trunk was especially atrophied, first, from the fifth to seventh intercostal spaces; secondly, from the tenth to eleventh ribs; thirdly, at the crista ilii. The entire left arm was atrophic, also the left leg and thigh. Frequent fibrillary twitchings in atrophic muscles; two foci of ossification in the quadriceps femoris. Sensibility intact.

Virchow has also described a case which was complicated with atrophy in the distribution of the scapular cutaneous nerves, and the musculo-spinal nerve of the same side of the body.

[1] Read before the Section on Neurology of the New York Academy of Medicine, Friday, December 10, 1886.

Mendel reports a case in a monomaniac which was associated with hemiatrophy of the tongue and the corresponding side of the body.

In Axmann and Hueter's case the patient had suffered, since the age of seven, from irregular spastic contractions of the muscles of mastication on the left side (motor branch of the trigeminus). These spasms were associated with increased sensibility in the distribution of the first and second branches of the trigeminus.

Seeligmueller reports the case of a blacksmith who received a violent blow in the left supraclavicular fossa. In addition to the symptoms of irritation of the sympathetic (dilatation of the left pupil, exophthalmus, pallor, and diminished temperature on the injured side), the left cheek underwent such marked atrophy in the course of a week as to be noticed even by the patient. A somewhat similar case is reported by Brunner.

Pathology.—We have been unable to find any records of a post-mortem examination in this disease, so that opinions with regard to its pathology must be purely theoretical. The theory of its sympathetic origin has met with some favor, but utterly fails, in our opinion, to explain the phenomena of the disease in the large majority of cases. With few exceptions the vaso-motor symptoms are either entirely absent or very slightly marked. It is true that atrophy of the face has been observed, as, for example, in Seeligmueller's case, in a few instances associated with the classical symptoms of paralysis or irritation of the cervical sympathetic, and perhaps the atrophic changes stand in a certain causal relation to the vaso-motor disturbances ; but such cases should not be included under the head of progressive facial hemiatrophy. This condition is, then, merely an incident in the disease of the sympathetic.

A number of facts seem to us to point to the origin of the disease in trophic fibres of the trigeminus nerve, or in its nucleus of origin. Nicaise's case points very decidedly in this direction. In this instance the history is identical with that of trigeminal neuralgia. It is true that hemiatrophy is rarely associated with purely neuralgic symptoms, but, on the other hand, neuralgia is rarely associated with atrophic symptoms. When it is so complicated it is indicative of an implication of the trophic fibres of the nerve.

Axmann and Hueter's case is also important in this direction. In this case the disease began with evidences of irritation of the motor root of the trigeminus, complicated with an affection of the first and second branches of the nerve. The fact that the disease has often been observed after injury to the face also possesses a similar significance.

But whether the lesion is to be located in the peripheral branches of the nerve, the Gasserian ganglion, or its nucleus of origin, is beyond our knowledge. Virchow believes that in many cases a primary inflammatory affection of the throat or face travels along the nerve-fibres to the ganglion.

According to Lande, the hemiatrophy is the result of a primary atrophy of the subcutaneous cellular and fatty tissue, exclusive of the elastic fibres. He believes that the elastic fibres draw the skin forcibly against the subjacent bones, and by compressing the blood-vessels of the skin and periosteum in this manner, cause anæmia and discoloration of the integument, atrophy of the bones, and also of the sebaceous glands and hair-follicles.

The disease can hardly be mistaken for any other, except, perhaps, for congenital asymmetry of the face. This sometimes is very marked and produces considerable deformity, but the imperfect development is confined mainly to the bones, which it affects more uniformly than in progressive facial hemiatrophy, and in addition the asymmetry is noticeable from early infancy. Such cases are seen most frequently in idiotic children.

A New Japanese Pharmacopœia has recently been issued. It is published in Latin as well as Japanese.

THE RELATION BETWEEN DRINKING-WATER AND TYPHOID FEVER.[1]

By DOWLING BENJAMIN, M.D.,

CAMDEN, N. J.

Typhoid fever is caused by a peculiar and specific poison. I do not know that this is denied to-day by anyone competent, from careful study and thorough investigation, to give trustworthy information on this subject. Does it arise *de novo?* All the investigations that I have made have proved to my mind that the poison which produces typhoid fever cannot be generated spontaneously, but must come from another source. I am aware that there are some gentlemen who even now believe that it originates *de novo*, and they give the examples and cases which prove to their minds the truth of such belief. But the cases cited as proofs are generally defective, and do not exclude the possibility of infection from a preceding case. Take, for example, the four instances given by Dr. R. W. Hutchinson, of Queens County, N. Y., published as late as October 9, 1886, in the *Medical and Surgical Reporter.*

I will not occupy your time by criticising all these cases, but will select the fourth, which seems to be the strongest, as follows :

"IV. In the last part of August, 1885, a party of young folks, numbering some fifteen, started out to spend the day on the banks of a creek near East Rockaway. They carried no water with them, but relied on securing a supply from a sunken barrel, near the creek, that had been used for that purpose for a number of years. On this occasion it was noticed that the water smelled and tasted badly, so much so that some of the party refused to drink it. Exactly one week from the day of the picnic most of them who had drunk the water, some nine in number, were stricken down abruptly with typhoid fever. I regret very much that I did not have the opportunity of examining the barrel, with its contents, immediately after the picnic, as I am now left in doubt as to the cause of the decomposition in the water. Shortly after the outbreak of the fever some person, fearing that others might drink, pulled up the barrel and destroyed the well. But from a number of reasons I can positively say that there was no possibility of the water being contaminated with the fecal matter of a patient suffering from typhoid fever, which is the recognized way of communicating the disease ; and if the germs of the disease did not originate *de novo* in the well-water, I ask the question, Where did they come from ?"

You see he gives no reason why the well could not be contaminated with typhoid fever, though he says he has a number of them—yet he says he had no opportunity of examining the barrel, nor its contents ; but he *heard* some of the party say that the water tasted and smelled badly. Notice that in less than seven days most of the party of nine who drank of the water were suddenly stricken down. This fact, in itself, might occasion some doubt of the fever being a true typhoid, as the incubation-period of typhoid fever is usually longer, though there are instances on record which would have a tendency to show that typhoid fever may occur with a shorter incubation-period than two weeks. Two weeks, however, is about the usual time.

What a blessing it might have been if the doctor had only told us the precious little secret of how he knew that no one had been in that vicinity, that his fecal matter might have affected the well.

Then take the cases cited by the illustrious Morchison, who has done so much for the thermometry of typhoid fever, but who has, perhaps, led astray more students of the origin of the poison than any other man. None of his cases are, in my opinion, conclusive, and this opinion is sustained, also, by the opinion of Dr. J.

---

[1] Read at the Twelfth Annual Meeting of the New Jersey Sanitary Association, Saturday, November 20, 1886.

H. Hutchinson, of Pennsylvania, who says, in an article on this subject, that the cases referred to are by no means convincing (see p. 256, "System of Medicine by American Authors," just published).

A case put forward by the advocates of the spontaneous-origin theory, as one of their strongest, is that reported by R. Bruce Lowe, Medical Officer of Health, Holmesley, Yorkshire, published in the *British Medical Journal* in 1880. "It occurred," he says, "in a lad who had not been away from home for months. No stranger had visited the house, and there was no fever in the district." But Mr. Lowe admits there was a case before, only eight months past, and only eight miles distant, and he does not prove there was no possibility of infection, either by domestic animals or by streams of water. It is a well-known fact that, when the great forests of *pine* are cut off the land in the northern part of the United States, there comes up a thick growth of *oak*-timber immediately succeeding; and the common opinion of people who notice this strange phenomenon is, that the little *oak-plants originate spontaneously* in the soil. I think you will hardly believe this correct; but the same agencies that sowed the original oak-seeds in the forest, it must be admitted, are fully competent to sow the seeds of typhoid fever in unexpected places occasionally. The man who starts out, in this present age of scientific research, to prove that typhoid fever originates *de novo* assumes a greater task than Hercules.

No combination, either of filth, fecal matter, or sewer-gas, has ever yet been discovered that will produce the disease.

What are the physical characteristics of the virus of typhoid fever? Is this virus a liquid, a solid, or a gas? Evidently it is matter of some kind. Inorganic matter may be either solid, liquid, or gas; organized matter is never liquid, never gas. We conclude it is not a gas for the following reasons:

First, the gas has not been isolated.

Second, it would be more apt to go through the air than otherwise, which is not the case with this virus.

Third, all known gases that affect the system profoundly, if they affect it at all, do so at once or in a few minutes after their reception into the system.

Can a dose of carbonic-acid gas, ammonia-gas, illuminating-gas, or any other poisonous gas, be taken and lie in the system for from two to six weeks, and then begin to develop a train of trouble, a uniform succession of symptoms, like typhoid fever, or small-pox, or any other of the zymotic diseases? Never. Is it a liquid, this virus? The same objections apply to this theory that apply to the theory of its being a gas. Is it composed of solid particles? If so, these particles must be of nearly the same specific gravity as water. There is no evidence to the contrary, at any rate, and these solid particles must be very small indeed, for water known to contain typhoid-fever poison is often apparently clear and bright. Filters do not seem capable of sieving out these particles, these poisonous particles, and this poisonous matter. At least water has been filtered through ten and even one hundred feet of sand and earth, coming out clear, but still bearing poison in sufficient quantities to produce fever and cause death. So far as is at present known the poison has not been filtered out of the water by any kind of filter. This would lead us to think it was really dissolved in the water, but for the fact that a system of very fine filtration has not been tried upon suspected water, and then the water given to persons to drink, to see if the disease would be produced by it. There is no case on record of any person ever having taken the disease from water that has been boiled, thus showing that, as far as known, the boiling-temperature destroys the poison.

The theory that the poison of typhoid is an organized poison, or germ, or bacillus, seems to explain its action more completely than any other. This phase of the subject was carefully discussed, and its progress given at length, by me in an essay written in 1876, and published in *The Country Practitioner*, vol. ii., Nos. 6 and 7. Whatever may be considered the nature of this virus, the fact *that water is its principal distributer is certain.* Indeed, a careful study of the cases and statistics that I have examined seems conclusive that at least ninety-five per cent. of the cases of typhoid fever come directly from the water. The poison which produces this disease does not go through the air. All physicians now permit people to go into the sick-room where this disease exists. Visitors, and those who wait on the patients, do not take the disease. The washer-woman has been known, in rare instances, to take the disease from the water containing the soiled linen, which has infected her hands and gotten into the mouth and absorbents. The infected wash-water is very often thrown on the ground near a well, or into the sewer, with the more poisonous dejecta. I have seen two cases that occurred among sailors who drank water from the Delaware River opposite the Philadelphia sewers.

There is one instance[1] where it has also been shown that cattle have been afflicted with this disease; but in tracing the disease still further back, it was found that the cattle caught the disease from drinking infected water, and thus the milk-supply has also been known to become affected. So the more we investigate the subject the more strikingly the fact stands out that water is the main habitat of the poison. Several facts show, also, that when water contains a little organic matter the virus will be active for at least a year, in still water, and very probably for a number of years, as some of the cases cited prove.

The ways in which a well, or a spring or stream, may become infected are so numerous and hard to trace that sometimes they defy detection. For instance, a man may leave the city, where typhoid prevails more or less at the time, and be either in the first stage of the disease in a slight form, or convalescing, or be a walking case, perhaps not even knowing what is the matter with himself, getting out of his carriage or a railroad-car, or takes his gun for a few hours' recreation, and, as it so often happens, is seized with a desire to evacuate the bowels, and this may take place in the vicinity of a spring or stream of water, whence will thus start up one or more cases of typhoid fever, and the manner in which that water became infected forever remain in doubt and a mystery. Even the persons living in that locality may not know of anything of the kind, or they may have known of the presence of such a person and may have forgotten it.

Recent investigations show the intimate relations of this disease to drinking-water to be so close and so constant that it is hardly ever worth while to think of any other source of the contagion.

One of the most remarkably clear examples of this relation of drinking-water to typhoid fever occurred last year at Plymouth, a small city in Luzerne County, Pa.; and for the invaluable lessons taught by this epidemic we owe much to the committee sent by the Mayor of Philadelphia to investigate the subject, and it is a plain and perfect explanation of the case. The explanation is as follows:

"The mountain-stream is a small one, running down over a rocky bed, and on a declivity not eighty feet from its bed a dwelling is situated, wherein, during January, February, and March, was located a case of typhoid fever that is only now convalescent, the worst period of the case being about the 30th of March. The attending nurse was in the habit, during each night, of carrying the excreta from the patient and depositing it on the ground toward the stream. The ground during all this time was frozen and covered with snow, until the thaw and rain already alluded to occurred. The poisonous character of the dejecta is not destroyed by freezing, but is only kept in a state of hibernation.

[1] Closten, Germany, 1878, Berlin. klin Wochenschrift.

"A great part of the three months' accumulation of dejecta was suddenly swept into the rapidly running stream, and reached the lower reservoir as quickly as a man walking fast could have arrived there.

"In fifteen days from this time the epidemic began, fifty cases occurring daily between the 10th and 20th of April. Up to the present, twelve hundred have been sick and one hundred have died out of a population of eight thousand. For the first three weeks the few people in the town who used well-water exclusively escaped the disease. The period of incubation varies between ten and twenty days, or longer, and therefore no other conclusion can be arrived at than that the infective poison existed in the mountain-water and originated from the one case of fever in the house on the side of the stream."

This entire and comprehensive report is on file in the Mayor's Office, Philadelphia, and is also published in the "Proceedings of the County Medical Society," May 13, 1885. The committee consisted of M. S. French, A.M., M.D., Surgeon of the Police Department of Philadelphia, and E. O. Shakespeare, A.M., M.D., Pathologist of the Philadelphia Hospital.

Last October a severe epidemic of typhoid was in progress in Imlaystown, N. J., about forty miles from Camden; and I went out there to investigate it, and was greatly assisted in so doing by the kindness of Dr. H. G. Norton.

I found that a brook about four feet wide runs through the village. A street runs parallel with the stream, about one hundred feet from it. A row of houses is situated between the brook and the street, and the back yards extend to the brook, about forty feet distant. Between the brook and the houses is situated a row of privies, and a row of wells for drinking-water. The privies are situated on the bank of the brook, so that the fecal matter from them has to run only a distance of three or four feet to get into the stream. The wells are between the stream and the dwelling-houses, and about thirty or forty feet from the brook. The somewhat impervious strata has a slight dip toward the well and underlies the locality. On measuring, it was found that the floor or bottom of the wells was not more than a few inches below the floor of the brook, and when the water was high in the brook it was also high in the wells, and that there was porous ground between the brook and the wells of the privies.

Beginning up the stream, and designating the houses, which are but a few feet apart—not over fifty feet—and numbering from 1 to 3, I will give you the following explanation:

In 1883 a family came to No. 1 suffering with "typhoid-malarial fever and diarrhœa." The children had fever and bowel-trouble, with diarrhœa, lasting for months, until the spring of 1885. On August 14, 1885, a young lady was taken with typhoid fever in this same house. On August 28th another young lady was taken with the disease in No. 2, the next house below—down the stream. August 27th, patient at No. 3 took the disease. September 12th another patient took the disease in No. 3. In September a relative of the family in No. 2 visited the town, drank the water, and died in a few weeks afterward of typhoid fever. September 30th a patient opposite to No. 2 took the disease. In the spring of 1886 the family had moved out of No. 2; the well had been kept closed, and had not been cleaned out. A new family moved into No. 2 in April or May, 1886. The boys drank the well-water, in spite of protests, and took the disease in June, 1886. One of the brothers died. The girls, who would not drink the water, escaped the disease.

An analysis of this water from the wells, by Professor H. B. Cornwall, of Princeton College, showed the water to be thoroughly contaminated with fecal matter. Evidently the virus had remained in one of these wells; a year had passed, and yet the winter had not been able to kill it.

The length of time that the virus will remain active has not been ascertained, but it is known to be years, in water that is not much disturbed.

I have cited these examples because they are so recent and so near at hand. Hundreds of instances might be cited, and the evidence piled up almost *ad libitum;* but, if further examples would not be superfluous in this paper, the time—twenty minutes—allotted to me would preclude my citing them here, and I might say now that much of the data upon which my remarks have been based is not included in this paper for the same reasons.

In the face of what is already known, I do not think that any student of sanitary science can deny that the poison of typhoid may be carried by the water-supply. I do not know that any do; *but the extent to which it is carried by water and the preventability of the same are the great points* that do not seem to be sufficiently appreciated by us, and scarcely appreciated at all by the people in general.

If the people can be made to understand that almost all the cases of typhoid fever come from the water-supply, and that there is no disease more easily prevented than this, we shall have accomplished the first great step toward the annihilation of one of the worst destroyers of mankind.

Look at the dreadful suffering caused in Philadelphia and Camden to-day by ignorance or indifference to these facts. Only a few days ago a noble wife and young mother died in our city of this dread disease, thus blighting the prospects of a happy family; and as I stood by her bedside I could but regret that another life had been needlessly sacrificed.

The city of Camden had deliberately connected the water-closets and sewers containing the poison with the water-supply, and then distributed it, thus laden with the deadly virus, to the inhabitants of this city, but a few hours after it had left the sewer. The husband of this lady is "as a lamb dumb before its shearers, it opens not its mouth;" so he paid his water-tax to the city, his wife drank the dearly bought "leprous distilment," and gives up her life as the result.

Is there no redress; is there no hope of escape for the people in these great cities? Must they continue to die by hundreds, as the death-returns show every year, at a greater cost and expense, indeed, than pure water could be procured for? Philadelphia also pours the poison into the cup, and then puts it to the lips of her most choice citizens, and kills off about seven hundred of them a year, according to the official report.

The disease cannot occur without the virus to produce it, and the virus can be kept out of the drinking-water, and it should be kept out at any cost. It would pay at *any* price. Every death that is preventable is needless, and is a reproach to the community. Dr. E. O. Shakespeare, an eminent investigator of contagious diseases, who has been sent abroad by the highest executive authority of the United States, to investigate the nature and causes of cholera, says, in the *New York Medical Journal*, January, 1885, that "epidemics of typhoid fever are absolutely preventable and controllable, and neglect to employ proper means to this end should be regarded as inexcusable."

Great reforms and revolutions have taken place within our own recollection; and the student of science dares to indulge the hope that, even during his short life, he may have the pleasure of seeing the death-rate from typhoid fever reduced more than ninety per cent.

ANTIPYRINE IN TETANUS.—Dr. A. A. Elliott, of Steubenville, O., suggests the employment of antipyrine in tetanus. His experience with it, he says, has been limited, but from its action in other conditions he believes that it should rank at the head of the list of relaxing remedies employed in tetanus.

LOCAL TREATMENT IN DIPHTHERIA.

REMARKS SUGGESTED BY THE DISCUSSION IN THE SECTION ON PRACTICE OF THE ACADEMY OF MEDICINE, MARCH 15TH.

BY C. E. BILLINGTON, M.D.,

NEW YORK.

THE conclusion of the important and valuable discussion which followed the reading of my paper on "Local Treatment in Diphtheria," before the Section on Practice of the Academy, on March 15th, was reached at so late an hour that I abstained from inflicting further remarks on an audience which had been both patient and kind. On reading over the report of that discussion, however, it seems to me to present an occasion for bringing out distinctly certain differences in the practical details of treatment which are worthy of the careful consideration of the profession, and this may now be done with more brevity and clearness than it could have been by me in extemporaneous speech.

First, as to the remarks of Dr. Jacobi. The fact that we agree so fully in general principles makes our differences in the mode of their application the more liable to be overlooked, although we have both been explicit in the statement of our methods.

As to the internal administration of the tincture of iron, we agree that this drug is "among the most reliable antiseptic and astringent agents." Dr. Jacobi says: "A child a year old must take at least four grammes daily; a child of three or four years, from eight to fifteen grammes. The chloride is to be mixed with water and glycerine in various proportions, so that a dose is taken every hour, every half-hour, every ten minutes. *Thus other local applications to the throat become mostly superfluous.*" (The italics are mine.) "Potassium or sodium chlorate, from one to four grammes daily, may be added with advantage."

A comparison of these remarks and the formulæ given by Dr. Jacobi, in his published works, with mine on this point will show that there are differences of detail to which my experience has, rightly or wrongly, taught me to attach no little importance. But the most notable difference is in the sentence which I have italicized. I have from the first of my publications insisted on the importance of also frequently spraying the throat with the mixture of carbolic acid and lime-water in all cases of any gravity in which it can possibly be done, and have considered this so valuable as to materially modify the prognosis, it being, unfortunately, impracticable in very young children, in whose cases I have recommended the occasional syringing of the throat, when indicated, for cleansing purposes.

Dr. Jacobi says: "The usefulness of lime-water . . . has been greatly over-estimated." Believing, as I do, that lime-water is one of the most valuable medicinal agents in our possession for combating diphtheria, I cannot, of course, regard this difference as otherwise than important.

Again, while there is complete concurrence between us as to the importance of nasal syringing, there is an equally marked difference between our methods in this procedure. Dr. Jacobi says, "The tendency to sepsis forbids a long intermission of them." "I again insist on their frequent repetition." (In his book, page 218, Dr. Jacobi says, "They must be made at least every hour.") "The whole procedure need not take more than half a minute for the two nostrils; the children may be raised in bed, a towel under their chins. One person holds the hands, the other sits behind and injects gently, in order not to injure the ears."

The salient points of the procedure as recommended by me may be recapitulated as follows: The patient, if too young to submit voluntarily to the operation, should be firmly held by a method described. The syringing should, if possible, always be performed by the physician himself. It should be continued on each occasion until, if it be possible, the passages are thoroughly cleansed. This should not usually be repeated oftener than two or three times in the twenty-four hours, for reasons stated. The first syringeful or two will often not go through at all. Then will come masses and strings of thick muco-pus, then, not infrequently, larger or smaller pieces of membrane. The syringing should be persevered with until the injected fluid comes through (by the throat and other nostril) clear and clean. The patient should have time to get his breath between the successive syringefuls. I commonly use half a pint, sometimes more, of the tepid salt-water, and the time required for a thorough cleansing is always several minutes.

By this method the physician, who should certainly in every grave case of diphtheria visit his patient, if possible, two or three times a day, and who is or should be an expert in such procedures and better able than anyone else to judge just how much or how little is requisite, performs it once for all—the patients during the intervals having a complete respite from the one measure in the whole treatment which is really unpleasant and fatiguing, and the nurse having quite enough left to her in the half-hourly giving of medicine and spraying, and the frequent giving of nourishment. By the other method a less thorough and complete cleansing (in "half a minute") is to be accomplished "every hour at least," and that, too, often by nurses who lack dexterity and judgment, and in many cases being possible only by force and with a renewed struggle. What more striking illustration of the danger of intrusting such delicate operations to average parents and nurses could possibly be imagined than the instances so graphically related by Dr. Jacobi of the performances of some "trained nurses?"

It must be admitted that, theoretically, the frequency required in the method described by Dr. Jacobi is apparently in more logical agreement with the principles of local treatment, which require frequent medication and spraying of the throat, but it should be remembered that this medication and spraying do not, or should not, cause local irritation or undue fatigue, either of which would be a contra-indication to them. Moreover, it may be added that two or three times a day is the limit of frequency beyond which the washing-out of an empyemic cavity or a septic uterus is not usually found useful, and while the analogy between the two is not perfect it may yet be sufficient to be suggestive. But the real question is, which of the two methods is the more efficient in accomplishing the object for which it is employed?—and this can, of course, be answered only by experience. My own experience I have stated, but my present object is far from dogmatic assertion, and still further from controversy, but is to place both methods clearly and fairly before the profession, so that each may be tested on its merits and neither suffer discredit from any faults or failures of the other. Dr. Jacobi, who agrees with me as to the importance of details in the treatment of diphtheria, will, I am certain, concur with me in this wish.

The device mentioned by Dr. Jacobi, of protecting the tip of the syringe with a rubber mounting, is an excellent one, and so is that of drawing a short bit of small soft-rubber tubing over the tip of a syringe, which was first mentioned by Dr. J. H. Douglas in the discussion of my paper in 1880, and again referred to by Dr. Delavan in this discussion; but any tip whatever may cause irritation and epistaxis in awkward hands, and even in expert ones, if the sudden movements of a young patient's head are not properly restrained.

The importance of the method which I have described, of holding a young child's head for nasal syringing, may be better enforced by a single illustrative case than by a great deal of argument. I was recently called in daily consultation in a case of nasal diphtheria by a physician whose compact and muscular frame leaves no room to doubt that he is one of the strongest men in the profession in this city. The patient was a babe four months old. On the

second day it was decided to syringe the nose, the syringing to be done by me. The babe was accordingly seated across its nurse's lap, its hands secured by her, and the basin in place. To show the doctor my way of holding a child's head, I stood behind it, and, leaning forward, placed my breast against it, holding it with a hand on each side, saying, "You see in that way the head is held as firmly as in a vise." The doctor then took his place behind the patient, and, standing erect, held the head between his hands, and with the smile of conscious strength said, "That head is in a vise." I accordingly placed the syringe in position for injection, not actually touching the mucous membrane, but at the first entrance of the fluid into the nostril the babe made a sudden downward movement of its head, in spite of the doctor's hands, sufficient to cause, from contact with the smooth tip of the syringe, a very slight hemorrhage. After that this exceptionally strong doctor, in holding that four-months-old baby, did not scorn to bend forward and place himself in the position which experience long ago taught me is necessary for really holding a child's head motionless.

Dr. Winters very truly stated that tact is of great importance in such procedures as nasal syringing; but the kind of tact which is most valuable is that which thoroughly accomplishes necessary objects with the least wear and tear to the patient.

The treatment of nasal diphtheria by means of any medicament applied by a medicine-dropper, as recommended by Dr. J. Lewis Smith, I cannot but regard as an error in the direction of dangerous inefficiency. The object of local treatment in diphtheria was well summed up by Dr. Loomis in the words, "cleanliness and disinfection," and these in this relation, as elsewhere, are usually attainable only by thorough, well-directed measures.

That spraying is a valuable method of cleansing and medicating the nasal passages in the treatment of catarrh is well known, and that it may sometimes be so in that of diphtheria in such expert hands as those of Drs. Bosworth and Delavan cannot be doubted; but the question remains, Can any method of cleansing them be in general at once as thorough and as unirritating and as well adapted to cause dilution and removal of poison and transudative interchange through diphtheritic membrane *in situ* as the flowing through them of a stream of antiseptic fluid from a syringe or douche? That these objects cannot commonly be effected with the ordinary throat-atomizer I am positive, as I have seen too many melancholy instances of fatal toxæmia from nasal diphtheria, the result of valuable time having been lost in relying on this inefficient substitute for syringing. It may be added that by no atomizer whatever can spray be made to enter one nostril and come out of the other as spray.

Finally, on the very interesting case related by Dr. William H. Thomson, which is typical of an important class, I will make the following remarks: Can Dr. Thomson assert that at the time of the first chill there was not the commencement of a local diphtheritic process in the posterior nares—or, possibly, in the trachea? It will, of course, be replied that there was no evidence of that condition. It is astonishing how little evidence is sometimes manifested of the presence of considerable amounts of diphtheritic membrane in concealed situations. I have seen quite a number of cases in which there was no evidence of it anywhere, except constitutional symptoms, in which I have, by syringing, washed pieces of membrane from the posterior nares several times in the presence of other physicians. In another case of an adult patient who had previously been frequently subject to grave catarrhal and bronchial attacks, another attack of a week's duration, similar in all its physical signs to the previous ones, under most competent and vigilant medical attendance, terminated fatally—no nasal obstruction, no croupy symptoms of respiration or voice, no visible membrane anywhere. There had been exposure to diphtheritic contagion two weeks before the attack. There were symptoms of toxæmia. The autopsy showed the trachea and bronchial tubes completely lined with diphtheritic membrane; none in the larynx; the posterior nares not examined.

I have no disposition to be "wise above what is written," and am far from asserting that there is never a case of "primarily constitutional" diphtheria; but, according to my experience, the more thoroughly such apparent cases of diphtheria without a *diphthera* are investigated, the fewer do they become.

THREE CASES OF ACETONÆMIA.

By WILLIAM S. CHEESMAN, M.D.,

AUBURN, N. Y.

Coma is one of the commonest modes of death in diabetes yet perhaps of no subject is our knowledge more imperfect. Not, however, from lack of investigators and theories. To unravel the mystery of this sudden and tragic *dénouement* many acute minds have been engaged, and many hypotheses framed. Changes in the nerve-centres, thickening of the blood from accumulation of sugar, uræmia, hyaline degeneration of the kidneys due to accumulation of glycogen in their epithelia, fatty embolism of the pulmonary vessels and consequent carbonic-acid poisoning, overloading of the blood with acids generated by too exclusive meat diet, thus impairing its ability to take up the carbonic dioxide produced in the tissues, and leading to self-suffocation, have been proposed and rejected. The theory which, though opinions are as yet by no means consentient, receives most credence, refers the symptoms to an auto-intoxication. As long ago as 1857 Bettyns called attention to the fruity odor of the urine and breath of comatose diabetics, an odor closely resembling that of pyro-acetic ether, or acetone. Kussmaul detected in such urine an ingredient yielding acetone under treatment with reagents. It was believed by him that acetone existed as such in the blood, exhaling in the breath and being excreted in the urine, and the condition was termed acetonæmia. But it is now supposed that some acetone-producing substance, probably aceto-acetic acid, is developed by fermentative changes of the saccharine matter in the blood in quantities sufficient to overwhelm consciousness and finally life itself.

Many researches have been made to test this theory, with results far from harmonious. Van Jacksch has shown that diacetic acid is present in the urine of patients suffering from the continued fevers, cancer of the stomach, pernicious anæmia, hydrophobia, and in small amounts even in health. Frerichs has given it to animals, by intravenous injection of doses as high as twenty grains, without effect. Hence many doubt the causal connection between saccharine decomposition and acetonæmia on the one hand, and between acetonæmia and diabetic coma on the other. Nevertheless a majority of recent writers favor the acetonæmic theory as covering most facts. And certainly it is difficult to refrain from connecting this sudden assemblage of nervous symptoms with the coincident appearance in the urine of a substance very unusual, to say the least, and in the experience of many observers peculiar to such cases.

I have encountered three cases of acetonæmia, so called. The first was that of a lady, a little past middle age, whom I saw on November 4, 1883, with Dr. Amanda Hickey, of Auburn. A year or more previously Dr. Hickey had discovered the existence of glycosuria. Under strict diet the daily amount of urine had diminished, but the patient had passed from under observation until the doctor was called to visit her on the date above given. We found her profoundly comatose; temperature normal; pulse, 130, and very weak; respiration, 30, and here and there over the chest the râles of pulmonary œdema. The family stated that two days pre-

viously the patient had visited Syracuse, and after her return had seemed better than for some time, but that on the morning of the day of our visit she had, without headache, nausea, or other prodroma, become rapidly drowsy, stupid, and comatose. Inquiry as to her previous health elicited the very curious circumstance that she had been under the medical direction of the family clergyman, who, trusting to homœopathic manuals and a urinometer, had concluded that a specific gravity of 1.022 ruled out sugar, and had given a rosy prognosis in connection with phosphoric acid. Nevertheless a specimen obtained by the catheter contained, not only sugar in very considerable amount, but albumen also, while with chloride of iron the rich Burgundy red supposed to indicate the presence of aceto-acetic acid was obtained, and later in the day casts were discovered by the microscope. The patient died that same evening.

The second case was that of a boy, aged ten, whom I first saw, November 20, 1883. He had had measles a month before, since which he had rapidly run down, with the symptoms of diabetes mellitus. The daily amount of urine was one gallon, and contained sugar in large quantity. The gums were ulcerated, teeth covered with sordes, and he was greatly emaciated and confined to the bed. A non-saccharine diet combined with tonics worked rapid improvement. The daily amount of urine fell to two quarts, strength and flesh returned, and in two weeks the lad was up and about. But he was a spoiled and self-willed creature, and extorted cookies and other sweets from his silly mother on the sly, so that sugar never entirely disappeared from the urine. In April, 1884, I was sent for again. He was in bed, quite rational, but with a temperature of 101°, and suffering somewhat from dyspnœa, though nothing abnormal could be found in the chest. He was then passing six quarts of urine a day, with a specific gravity of 1.012, and containing sugar, albumen, and casts. With chloride of iron the wine-colored acetone reaction was struck, and I ventured to predict the near approach of coma. On the 19th the prediction was verified, and on the 20th he died.

It is true that in both of these cases a nephritis had been set up by the long-continued passage of sugar; yet in neither case did the coma seem uræmic. No anasarca, headache, vomiting, amaurosis, or convulsions preceded. It came abruptly, unannounced, and when the patients were apparently in good health. Moreover, the chloride of iron revealed the presence of a urinary ingredient not found in ordinary uræmia.

In the middle of February last a gentleman aged fifty-seven applied for relief from a gangrenous ulcer of the left leg. This was poulticed till the slough separated, when iodoform was used. The ulcer healed very slowly, and I was puzzled to account for its continued unhealthy appearance. On March 4th the patient called, complaining of shortness of breath and a feeling of oppression in the præcordium. Examination of the chest revealed nothing to explain this, and as he never had had asthma, I felt inclined to listen to his own interpretation of the matter, viz., indigestion. But on the 7th I was sent for to visit him. The same oppression of breathing continued. He had been awakened several times in the night with præcordial distress. As he walked up and down the room he breathed much more deeply, though no more frequently, than natural, and would strike his sternum and exclaim, "I'm all right every way but here; the trouble is right here." I examined heart and lungs again, finding nothing wrong. His wife, on being questioned, stated that he had lost weight recently. Then a suspicion flashed upon me, and I asked for a specimen of urine. Its specific gravity was 1.030; it contained neither albumen nor casts, but sugar; and with the chloride of iron the Burgundy red of acetonuria was produced.

Though knowing that in some reported cases coma had been precipitated by sudden withdrawal of starchy foods, I thought that, as acetonæmia had already developed, nothing worse could well happen, and so put the patient on broths and milk, and sent him to bed, a cathartic and diaphoretics being at once administered.

During the twelve ensuing days his condition grew gradually worse. The oppression in the chest continued. The respiration, though usually not above 22, was at altimes deep and labored, and he suffered occasional parl oxysms of dyspnœa, closely resembling those of spasmodic asthma. These occurred oftenest at night, awaking and compelling him to lean forward, grasp the chair-arms, and labor for air. At such times the ear could rarely detect a few râles in his chest, never the wheezing and whistling of true asthma, and commonly nothing whatsoever. The temperature remained normal throughout. The pulse ran at about 120, and from the first was noticeably feeble, though regular. On auscultating the heart no abnormal sounds were heard, and no history of preceding heart-lesion, or of any disease likely to cause it, was obtainable. By the end of the first week œdema of the feet and ankles began. Never were there any head symptoms. The patient was drowsy at times, but only from losing sleep. Nothing approaching somnolency or stupor was observed. The stomach did its work well, vomiting occurring but on one day, when it was due to quebracho. The patient had one bloody stool; at other times the movements were regular and natural. Treatment was directed to meet the symptoms. The dyspnœa was best relieved by morphine, in combination with spts. æth. comp. Inhalations of oxygen, amyl. nit., fumes of nitre, smoking stramonium, quebracho, etc., were finally abandoned for this. Stimulants were freely employed. Meanwhile the urine continued, in spite of change of diet, to contain sugar in large amount. Its daily quantity averaged two quarts, the specific gravity ranging from 1.020 to 1.032. No albumen or casts were ever found. During the first three days its odor resembled that of amyl nitrite. The acetone reactions with ferric chloride, sulphuric acid, potassic cyanide, and caustic potash, gradually grew fainter, however, and the fruity odor of breath and urine coincidently disappeared. On March 18th I observed some subsultus. He was seen that day by Dr. Theodore Dimon, who confirmed the diagnosis. The next morning (the 19th), after an unusually comfortable night, and after having expressed himself as feeling better than at any time, the patient suddenly fell back in his chair dead. A specimen of urine, voided shortly before, contained sugar and acetone well marked again. No post-mortem was made.

This case affords further confirmation of the prognostic value of the acetone tests. Though instances are recorded of recovery out of even coma itself, yet these are too rare to alleviate the extreme gravity of the outlook when once the urine turns red with ferric chloride.

The Prevention of Mammary Abscess by Antisepsis.—Regarding this subject, alluded to in an article by Dr. E. Brush (The Medical Record, March 26, 1887), Dr. A. Rose, of this city, says: "It might be more instructive to speak of the principle of treatment than to mention only one certain remedy, while many others of the same class have absolutely the same effect. It is a well-established fact that mammary abscesses are caused by infection entering through cracks or sores of the nipples. Any measure which protects the nipples, that they may not crack or become sore, and, above all, which secure their *aseptic* condition previous to and during lactation, will surely and always prevent mammary abscess. Dr. Brush's treatment is simply antiseptic."

Treatment of Painful Hæmorrhoids.—Dr. Thomas H. Kinnard (*Pacific Med. and Surg. Journ.*) has treated twenty cases of painful hæmorrhoids successfully by anointing them with extract of garlic, one part; olive-oil, two parts. If they are internal, he injects a drachm of the mixture into the rectum.

Clinical Department.

FRACTURE OF THE INTERNAL EPICONDYLE TREATED WITHOUT SPLINTS.

Dr. G. T. Loomis, of Minneapolis, Minn., reports the following case: "H. D——, aged nine, was thrown forcibly upon the ice, striking his elbow, and was brought immediately to my office. He was suffering severe pain about the internal condyle, which was increased by any attempt at extension, although the latter could easily be done. The arm was semiflexed, the point of the condyle being displaced downward one-half inch, and could be moved easily in any direction. I flexed the arm and reduced the displacement easily, and applied a bandage firmly, the arm being held in a sling. No pain and little swelling next day. The dressing was left in position one week, and the arm could then be extended about one-half. The bone remained in position. Passive motion was made nearly every day for four weeks, the arm swinging at the side without bandage. At the present time, two months after the accident, the boy can extend and flex the arm nearly as well as ever."

MARGINAL PLACENTA PRÆVIA RELIEVED SPONTANEOUSLY.

Dr. Daniel Brown, of this city, writes that he was called about two o'clock one morning to attend a woman in confinement. The woman lived in Thirty-sixth Street, and much time had been lost, as the messenger had gone first to Broome Street to call the family physician, Dr. Agan. The latter was occupied with another case, and referred the husband to Dr. Brown. When he reached the bedside he found the patient sitting on the edge of the bed—she had refused to lie down during the previous time—her night-dress, the floor, and part of the bed were pretty well saturated with blood. As soon as possible the unpleasant task of finding out the depth of his difficulties and responsibilities was entered upon, and to his great relief he found that though the pains were very sluggish at this time the head was firmly engaged at the superior strait, and only a slight oozing of blood continued. In fact, all danger was over, and all he had to do was to attend a tedious delivery, which was accomplished before daylight. Dr. Agan since reports both mother and child doing well. After the placenta was delivered it plainly showed the extent of the part presenting—the bruised and clotted appearance in the form of a crescent-shaped border, about three-fourths of an inch in its widest diameter. Dr. Brown asks whether a spontaneous cure of this troublesome and dangerous complication is often met with.

THE TREATMENT OF NEPHRO-LITHIASIS.

Dr. J. B. Potsdamer, of Philadelphia, submits the following: "The objects to be attained in the treatment of this disease are: 1, To remove the already formed concretions; and 2, to prevent their further formation. The latter object is, to a great extent, accomplished by a proper regulation of the diet. The researches of Lehmann, Heinrich, and others, prove that there is an increased excretion of uric acid when the amount of animal food consumed is augmented; that is to say, an almost exclusive flesh diet promotes the formation of renal sand. As other articles of food cause an increased excretion of uric acid, general moderation in eating must be observed, the patient confining himself to white meats and substances easy of digestion. Vigorous individuals accustomed to high living should take active exercise, and liquors and highly seasoned foods must be forbidden. The best solvents for sand and gravel which are composed of uric acid, urates of ammonia, and oxalate of lime, are the alkalies and alkaline salts. The sulphates are of inestimable value in this connection, especially the waters containing Glauber's salt. The phosphates have also been strongly recommended. Waters containing the carbonates and free carbonic acid are of value, especially when in combination with the other salts. The free use of plain water will aid the removal of calculi; but unless intelligently administered, the use of the alkalies will prove injurious. They must not be given in such quantities as to give the urine an alkaline reaction. If this should occur, the urates and uric acid will be held in solution, but there will be a precipitation of the earthy phosphates. The following salts are the most beneficial, in the order named: Sulphate of sodium, carbonate of sodium, and the phosphates; particularly the soda salt. Any natural mineral water that will combine all or almost all of the above should, at least theoretically, be the best remedy for this disease.

The Carlsbad waters are rich in those very salts which have been found to be the best remedial agents in nephro-lithiasis, and experience has taught that the administration of the alkaline waters is superior to taking water and the alkalies separately, and that the best results have been obtained from the Carlsbad waters.

In Ebstein's article on the treatment of nephro-lithiasis, in Ziemssen's "Cyclopædia of the Practice of Medicine," vol. xv., the author speaks in the highest terms of these waters. They should be taken hot. The patient should begin by taking four gobletfuls a day. This may be increased up to the point when the urine shows a tendency to become alkaline, but not beyond this point; for, as was stated above, the production of alkaline urine must be avoided.

THE EARLY TREATMENT OF PRESSURE-PARALYSIS OF THE RADIAL NERVE.

Dr. William Browning, of Brooklyn, sends the following communication: "Among the causes of radial paralysis, temporary compression of the musculo-spiral nerve occurs with varying frequency. The idea of many observers, that wrist-drop is almost synonymous with lead-poisoning, is not borne out by the very different experience of others. In the three years from 1884 to 1886 sixteen cases of wrist-drop due to pressure—all in males and of the unilateral form—applied for treatment at the Long Island College Dispensary, as against only eight cases due to plumbism—two in females and all but two bilateral. In two of these sixteen cases the etiology was not quite certain, nor, of course, has it been possible to follow up all of them. Compression by growths, cicatrices, etc., and gross injury, such as crushing the nerve, constitute severer affections. The prognosis, as given by most writers, is not favorable to an early recovery, several months usually elapsing, though a small proportion of cases recover in a short time. As recently stated by Vulpian and Déjerine, degeneration, with its attendant electrical reactions, does not usually follow, except in the long supinator muscle. Such absence of other than functional change indicates that the lesion in this class of cases is of a slight nature, and ought to be easily remediable. In my experience this is also the case, provided treatment is instituted within the first few days. If much over a week has elapsed, the trouble is inclined to become more obstinate. There is one symptom bearing directly on treatment which does not seem to have been specially observed, and to which it is desired to call particular attention. If in such a case the course of the musculo-spiral nerve around the back of the arm be closely examined early in the trouble, a tender joint can generally, if not always, be discovered. This corresponds, approximately at least, to the seat of injury, and must represent a slight inflammation in or about the nerve. The later obstinacy of the paralysis, when left undisturbed, is doubtless owing to this very

limited process. No autopsy in such a trouble has been reported, and hence the exact nature of the lesion is unknown. Déjerine and Vulpian were unsuccessful in their attempts at producing a like paralysis in dogs. The first step in the early treatment, then, ought to be directed to this tender point. Strong counter-irritation, or local derivation in the shape of a fly-blister immediately over the tender spot, has, in my experience, proved adequate. Next, the forearm may be douched, alternately hot and cold, and well shampooed. Finally, a strong faradic current is applied. Some numbness is usually complained of along the radial side of the dorsum of the hand and forearm. This region is first touched with the faradic brush. Then with ordinary electrodes a current is used of sufficient strength to cause ample contractions in the muscles. Voluntary control over the paralyzed parts is seen to gradually and completely return, a couple of applications of the current at an interval of as many days being all that is required if a cure is to be effected in this way. Where it has been possible to carry out this plan there has been no failure. Otherwise success is uncertain, as *e.g.*, in one patient where sixteen days had elapsed. No tender spot along the nerve could be made out, and the remaining treatment proved of little immediate avail. Perhaps if treatment in the later stages of the trouble were directed to the point of injury, more success would be achieved. The nerve below reacts electrically, though above it neither responds to the will nor to the current; hence the point of injury can be determined even after the tenderness above described has passed away. The same general method would be applicable to like trouble in any other nerve."

Progress of Medical Science.

The Relative Digestibility of the Chief Albuminoids. — Dr. James Fraser has made a series of experiments (*The Lancet*) to determine the digestibility of various proteids. The substances experimented upon were: Raw albumen, serum and egg; cooked albumen, also serum and egg; globulins, raw and cooked; myosin; derived albumen, viz., syntonin, alkali-albumen, casein; vegetable albumen, impure gluten. Each of these was subjected to six hours' peptic digestion, then for six hours to pancreatic digestion; at the end of this time they were placed in a temperature of 176° F., and dialysis was allowed to proceed for twenty-four hours. The author gives the result of his researches in a tabulated form, and estimates the amount of peptones dialyzed as nitrogen. The most digestible albuminoid was found to be cooked myosin; then came raw serum-albumen, after which the order was as follows: syntonin, alkali-albumen, raw-egg albumen, casein, cooked-egg albumen, cooked serum-albumen, raw myosin, and gluten. It might have been expected that syntonin would have headed the list, as it is partly digested beforehand, yet it was not far from being ahead of the others. These results apply to the albuminoids after they had gone through the processes of peptic and pancreatic digestion, as well as dialysis. Each albuminoid substance was reduced to a dry solid state, and, on taking the percentage relation between the amounts dialyzed and the amount of albuminoid actually used, it was found that in no case did fifty per cent. of the dry solids pass through the dialyzer, this depending rather on the short period of dialysis than on imperfect peptonization. On examining the tables showing the amounts of nitrogen dialyzed in each stage of the experiment, it is seen that in no case did two per cent. pass through the dialyzer during peptic digestion; the uncooked albumens gave the highest peptic results, and syntonin next. Turning to tryptic digestion, cooked myosin heads the list, then the order is as follows: raw serum-albumen, raw-egg albumen, syntonin, cooked serum-albumen, raw myosin, casein, gluten, and cooked-egg albumen last; this experiment being conducted in an alkaline menstruum, those substances which are most easily soluble in an alkaline solution have naturally an advantage in digestion; hence the high position of raw albumens and of syntonin. During the two stages of peptic and pancreatic digestion, peptones were formed more rapidly than they could pass away through the parchment paper, and accumulated in the dialyzers, so that when the ferment was killed by heating to 176° F., and dialysis was continued for twenty-four hours, a larger proportion of crystalloid matter passed through than in the former stages; these peptones were both of peptic and tryptic formations, as in the case of those under the head of pancreatic digestion. The largest proportionate result was found in the case of cooked myosin, which was not far ahead of raw serum-albumen; then came cooked-egg albumen, alkali-albumen, casein, cooked serum-albumen, raw-egg albumen, raw myosin, and lastly gluten. Many of these albuminoid sare not ordinarily used as foods; for instance, serum-albumen, raw myosin, syntonin, alkali-albumen, though they are the most digestible of the albuminoids. By utilizing the results of these experiments much valuable aid can be given to those who require good nutritious diet for invalids unable to digest solid food. Beef-tea, as ordinarily prepared, is of little nutritive value; but if the white of an egg be mixed with a cup of beef tea and heated to about 160° F., the value of the beef-tea is greatly enhanced. Again, if minced raw beef be just covered with very weak hydrochloric acid (four drops of acid to one pint of water) and left to macerate for the night, the liquid strained off and squeezed out of the flesh by wringing in a cloth contains so much syntonin as to make it highly nutritious when neutralized; such a liquid will remain clear after boiling to remove the raw flavor. In cases where the digestive powers are not in abeyance, one may give by mouth or by enemata one or more of the various forms of peptonized foods or fluids that are now in the market. In cases where the digestive powers are lost in the stomach, but retained in the intestine, or where some obstruction to the passage of food into the stomach exists, the above experiments will give much help in treatment. The experiments with casein and gluten show that there are very few worse foods for a delicate stomach than the usual bread and milk; whey is a mildly nutritive fluid, and easily digested. In cases where it is desired to feed the patient through the intestine, those substances found soluble in alkaline fluids, and therefore easily acted on by the pancreatic juice—viz., raw albumen, syntonin, or alkali-albumen—may be used alone or dissolved in some meat-tea.

Valvular Disease of the Heart without Serious Symptoms.—Sir Andrew Clark has published recently some remarks concerning cases of valvular disease of the heart, known to have existed for over five years without causing serious symptoms. He sums up his conclusions as follows (*The British Medical Journal*, February 19, 1887): 1. There are many persons with long-standing valvular disease of the heart, engaged in the active business of live, who without any symptom of heart-disorder have enjoyed good health, and have reached an advanced age. 2. The mitral regurgitant murmurs so often encountered in chorea, for the most part, disappear within eight or nine years of the attack. 3. Valvular inflammations, and their effects arising in the course of rheumatic fever, do sometimes disappear, and leave behind no clinical evidence of their former existence; this occurring for the most part in the young, also occurs sometimes in the middle-aged. 4. The signs of valvular defects arising out of the degenerative changes of middle life do also, on rare occasions, disappear, and when circulatory and respiratory disturbances accompany their commencement they sometimes subside and permit of apparently complete readjustment. 5. As there must be in the histories, habits, occupations, and surroundings of patients

with valvular disease conditions which in one case bring about secondary disorders, and in another case exempt it from them, it is desirable that the respective *differentiæ* should be discovered, and made capable of application to practice. 6. Any systematic and critical study of this subject likely to lead to practical issues could be undertaken by the Collective Investigation Committee, and not by it unless actively assisted by experienced general practitioners who possess, in a special manner, the knowledge necessary to the end in view. 7. A joint inquiry of the kind proposed, conducted with due patience, discrimination, and accuracy, would greatly extend our knowledge of the natural history of diseases of the heart, and largely increase our means of assisting those who suffer from them.

Intra-peritoneal Hemorrhage in a Newly-born Infant.—In connection with the subject of hemorrhages of the newly born, so recently brought to our notice by Dr. E. C. Wendt (The Medical Record, February 19, 1887), the following case, reported at a late meeting of the London Medical Society (*The Lancet*), will be read with interest. The case was observed by Dr. Keser. The child was born at full term on April 29th, and the labor was normal. The infant was in a state of apparent asphyxia, but respiration was easily established. There was slight subconjunctival hemorrhage on the right side. On May 1st swelling of the scrotum was observed, and the penis was edematous. On May 4th the scrotum was much more swollen. The temperature in the rectum was 98°. The abdomen became swollen and the lips were pale. The cord separated on that day without hemorrhage. The child died on the ninth day. There was an ecchymosis in the middle of the back. Melæna or hæmatemesis was not observed. The spleen was enlarged; the upper half was swollen and congested and very dark from hemorrhage, which seemed to have come from a lesion that looked like an infarct. The peritoneal cavity was full of dark, fluid blood, the amount escaping being about eight ounces. The splenic artery appeared to be normal, as well as the other branches of the aorta. There was no hemorrhage or infarcts in any other organs. The mother had had eight pregnancies. The first child died at the age of eighteen days, but the cause of death was unknown. After this child five still-births occurred. The seventh child was born at full term, was nursed by the mother, and remained well until the end of the fourth week, when epistaxis set in, followed by hæmatemesis and melæna; large ecchymoses appeared on the trunk and limbs, and death ensued after a week's illness. The mother had no tendency to metrorrhagia or to any other form of hemorrhage. There was no hæmophilic history so far as could be obtained.

The Palliative Treatment of Carcinoma of the Uterus.—Dr. Gaches Sarrante reports a number of cases of uterine cancer, which could not be operated upon, treated with a fair measure of success in the following manner: The genital canal was first very thoroughly disinfected by means of copious injections of sublimate solution, and then all sloughs and loosened pieces of the cancerous tissue were removed, care being taken not to disturb those that were adherent, as it was desired to avoid all hemorrhage. Tampons, soaked in a four-per-cent. chloral solution, and then spread over with powdered iodoform, were now applied to the cancerous ulcer or inserted into the cavity, if any existed, formed by the loss of substance. This was applied so that the entire diseased surface was brought in contact with the medicated tampon, and was retained *in situ* by a vaginal tampon, being left undisturbed until the next visit. The results of this method of treatment are summarized as follows: 1, Hemorrhages, even when profuse, are absolutely stilled and prevented from recurring; 2, the ichorous surface of the tumor is cleansed, and presents the clear, red appearance of healthy granulation-tissue; 3, the pain is entirely relieved; 4, the general health of the patients is greatly improved and the discharge loses its fetid odor, so that the women are able to go out and enjoy social companionship without the consciousness of being an offence to their friends. The iodoformized tampons were applied three times a week.—*Memorabilien*, November 4, 1886.

The Action of Tea and Coffee.—Dr. J. W. Putnam is opposed to the indiscriminate use of tea and coffee, especially in the young. He says (*The Medical Press of Western New York*, January, 1887) that they retard digestion; they retard destructive metamorphosis; they are cerebral stimulants; they are tonics; they are not food; coffee is a diuretic and antispasmodic. Bearing this in mind he thinks that it is easy for each to draw his own conclusions. Their prohibition or their use can be advised as special cases may demand. He is of opinion that "against the practice of giving tea and coffee to children we cannot speak too strongly. Childhood is the period when the nervous activity is at its greatest. The brain is ever busy in receiving new impressions. Reflex action, co-ordination of muscles, and the special senses are all under a constant course of training. The nervous system is pushed to its utmost capacity, and long is the list of victims that follow its over-stimulation. In these little people nothing but harm can come from the use of such cerebral stimulants as tea and coffee. Bad, then, as this practice is, let us as physicians be aggressive in its prohibition. Do not be satisfied by answering No, when asked as to its use, but let us educate the families with whom we come in contact that such practice is evil."

The Immediate Cause of Death in Malignant Cases of Fever.—At a recent meeting of the Sheffield Medico-Chirurgical Society (*The British Medical Journal*) Dr. C. H. Willey read a paper on this subject. The cases under consideration were those of scarlet fever and small-pox in which unconsciousness and death ensued at an extremely early stage. The pathology of this condition had not been explained. The conclusions to which Dr. Willey had arrived were based on clinical observations and post-mortem examinations in twenty-five of these malignant cases. The chief factors in the investigation appeared to him to be that the fatal symptoms were, in each case, those of a rapidly failing circulation, and that, after death, the heart-chambers, especially the right, were completely filled with white, jelly-like clot, which was, he said, clearly of ante-mortem formation. The failure of the circulation (particularly in small-pox cases) ensues with great suddenness, and the question arose, Was this failure or the thrombosis the primary condition? Evidence from the main symptoms, and from such invariably accompanying ones as pulmonary œdema and copious diarrhœa, Dr. Willey said, goes to show that a failure of the circulation is the primary cause of death, and, further, that not only is the heart paralyzed, but the entire arterial system—in fact, a total collapse of blood-pressure throughout the vascular system is brought about with more or less suddenness by a functional failure of the sympathetic nervous system, governing, as it does, the cardio-motor and vaso-motor functions. The pulmonary œdema and the profuse intestinal flux are due to the same cause; they are undoubtedly associated with a greatly diminished blood-tension in the arterial system.

Midwives in Finland.—The obligatory course of studies for midwives in Finland is of one year's duration. There is a supplementary course of two weeks, for those who have shown unusual aptitude, in obstetrical operations, such as embryotomy, the use of the forceps, etc. The students are almost all women of the lower classes, and the only requirements are that they shall be able to read and write. They are allowed to perform operations only when it is impossible to procure the services of a physician.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, April 16, 1887.

INTRA-MUSCULAR INJECTIONS OF QUININE.

IN cases in which quinine is indicated, but in which it is not well borne by the stomach, attempts have often been made to introduce the remedy subcutaneously. This method sometimes gives excellent results, but it has its inconveniences and its dangers as well. It is painful in its immediate effects, and it is also apt to leave a tenderness of the subcutaneous tissues which precludes, for a longer or shorter period, any repetition of the injections in that neighborhood. It is said to have caused tetanus, and it not infrequently gives rise to the formation of troublesome abscesses, upon which, in one case at least, pyæmia has supervened. These dangers, in most cases, more than counterbalance the good to be derived from quinine administered in this way, especially when the rectum is still available as an avenue for the entrance of the drug into the system.

Dr. Carlo Bareggi was led by these considerations to make a thorough trial of deep intra-muscular injections, which have been made before, but never, we believe, on so extended a scale. His article, accompanied by a tabulated statement of the cases and of the results of treatment, is published in the *Gazzetta degli Ospitali*, No. 9, 1887. The number of patients subjected to experiment was only eighteen, but the total number of injections made amounted to the very considerable figure of six hundred and fifty-three, so that the conclusions drawn by the author as to the value and the innocuity of the method would seem to be justified by a tolerably extensive experience.

The injections were practised only in those cases in which they were demanded by reason of an intolerance for the drug on the part of the stomach and rectum. The salt used was the muriate of quinine, dissolved in distilled water in the proportion of one part to five, and from two to ten injections, of fifteen grains of the salt each, were made in a day. Every precaution was, of course, taken to insure absolute purity of the solution and cleanliness of the syringe. The needle was passed deeply into the gluteal region, the skin of the nates having been previously washed and cleansed with carbolated oil.

The injections were in all cases well borne, and in none did inflammation or abscess follow. The cases treated in this way were: Nine of malarial fever, eight of typhoid fever, and one of pyæmia following urethral abscess. The author insists upon the selection of the muscular region of the nates as the site for the injections, for in one case in which the lumbar region was chosen a very large and troublesome abscess was produced. In every case a complete cure was obtained. Dr. Bareggi claims, therefore, that this method is free from danger, and that it may safely be resorted to when, from any cause, it is impossible or impracticable to give quinine by the mouth or rectum.

THE EFFECTS OF IMMOBILIZATION UPON THE ARTICULATIONS.

IT is a curious fact in medicine that questions which would seem to be capable of actual demonstration, not only by experiment but also by the observation of daily occurring clinical facts, are still subjects of warm dispute, and are yet apparently as far from being conclusively settled as on the day when they were first broached. This is the case in regard to a question apparently so easy of solution as that of the behavior of joints after long immobilization. Many authorities teach that the retention of an articulation in a fixed position for any length of time will inevitably lead to true anchylosis, while others maintain with equal positiveness that no permanent impairment of the functions of the joint can be so caused.

In the hope of arriving at some satisfactory solution of this vexed problem, Dr. Albert Moll made a number of experiments on rabbits by immobilizing their hind legs in plaster-of-Paris splints (*Virchow's Archiv*). He made three sets of experiments. In the first, sound legs only were immobilized; in the second, the bone was broken before the application of the splint; and in the third, the animal was allowed to run around freely for a time after the removal of the retaining apparatus before the joint was examined. No passive movements, however, were made in this last series of experiments—the animals were merely permitted to run free, as they would or could.

In the first series of cases there was no anchylosis, nor even an approach to it; the joints which had been immobilized were entirely free from any traces of inflammatory action. In the second series some cases of articular inflammation were observed. This condition was more frequently present when the fractures were compound and situated in close proximity to the joints, although not involving them. Whether this inflammation would always result in anchylosis the author was unable to say. He had observed such a termination in but one case. In some of the cases of the third series there was complete restoration of the function of the joint, but in others a certain degree of stiffness remained, though probably this could have been overcome by passive motion. The limitation of motion was apparently due, in some cases at least, to certain more or less serious changes taking place within or about the joint, such as destruction of the articular cartilage, shortening of the ligaments, shrinking of the capsule, muscular atrophy, etc.

Dr. Moll concluded from these experiments that a sound limb could, with perfect safety, be immobilized for an indefinite period, and in cases of simple fracture, not seated near the joint, there was no danger of anchylosis.

In compound fractures, however, especially those in the neighborhood of an articulation, there was danger of joint inflammation and subsequent anchylosis, but even here the evil result should probably be referred to the fracture rather than to the immobilization of the articulation.

A CONTRIBUTION TO THE SURGERY OF THE LUNGS.

The fact that the surgery of the lungs is still in its infancy, and that the justifiability of an operation for pulmonary tuberculosis is as yet *sub judice*, is a sufficient apology for the notice of the following case, reported by Dr. A. Casini in the *Rivista Clinica e Terapeutica* for January, 1887.

The patient was a man, forty years of age, an inmate of the Hospital for Incurables, at Naples. Examination revealed the presence of an apparently superficial cavity in the right mammary region, extending from the third to the fifth intercostal space. There were night-sweats, fever, cough, with purulent expectoration, diarrhœa, and all the other general symptoms of tuberculosis. Examination of the sputa showed the presence of tubercle bacilli. Dr. Casini resected the fifth rib, and would have resected the fourth, but was obliged to abandon the operation temporarily on account of evidences of heart-failure. The following day the cavity was opened and washed out with a disinfectant solution, and was subsequently treated with insufflations of iodoform, and irrigations with a 1 to 1,000 solution of corrosive sublimate. The expectoration at once began to diminish in quantity, and within ten days had lost its purulent character, while no more bacilli were to be found. The patient was discharged, and returned for examination some months later presenting no symptoms of pulmonary or general tuberculosis.

Emboldened by his success in this instance, the author formulates the following conclusions:

1. Surgical intervention will arrest the tubercular process when it is circumscribed in the lung. Opening, evacuating, and washing out a pulmonary cavity is the same, saving the greater or less difficulty of the operation itself, as opening a tubercular cavity in a bone, or excising a tubercular product in the skin.

2. A pulmonary cavity, when circumscribed, is to be regarded as a local tuberculosis, and any extension, metastasis, or generalization of the disease may be averted by an early and a thorough removal of the morbid process.

We should hesitate to regard these conclusions of Dr. Casini in the light of axioms for the guidance of pulmonary therapeutists, if we may be allowed, for brevity's sake to speak of the latter as a distinct class of practitioners. But the case reported is an interesting and instructive one, by reason of its successful issue, and it is a valuable contribution to the literature of pulmonary surgery.

INTESTINAL WORMS AND PERNICIOUS ANÆMIA.

Despite the not inconsiderable amount of study which has been devoted to the causes of this condition, there are still many cases of disease, in which anæmia is the most prominent or the sole symptom, which progress to a fatal issue without any sufficient reason being discoverable.

In a recent number of the *Finska Läkaresällskapets Handlingar*, Dr. J. W. Runeberg advances the opinion that the presence of intestinal worms may account for many of these cases. While in charge of the Helsingfors Hospital, from 1883 to 1886, he saw nineteen cases of pernicious anæmia, in twelve of which he found tapeworm (Bothriocephalus latus) and in one lumbricoid worms. Remedies were directed to the destruction of these parasites, and but one of the cases died, whereas in the years immediately preceding there had been nine fatal cases.

The author believes that the parasites were the cause of the anæmia, and that their destruction was the only means of averting a fatal issue. He regards the disturbance of intestinal function and the nervous irritation caused by the presence of the worms as the active causal agents, and believes that the anæmia of anchylostoma duodenale is produced in this way rather than by the loss of blood from the bites of the parasite.

It is not improbable that the unrecognized presence of intestinal worms may be a factor in the production of some cases of so-called pernicious anæmia, and it is a wise precaution to examine the stools in all such cases for the eggs of the parasites.

THE INFLUENCE OF THE BILE UPON THE CARDIAC MOVEMENTS.

A slow pulse is one of the well-known symptoms of catarrhal icterus or of other hepatic affections in which jaundice is present. It has been abundantly proven, notwithstanding the assertions to the contrary of Vierordt, that this symptom is due to the action of the bile upon the heart. But what particular constituents of the bile exert this action, and how the effect is produced, are questions which have hitherto not been satisfactorily answered. Feltz and Ritter have, indeed, shown by experiments that the slowing of the heart's action is due to the presence of the biliary acids, and that the cholesterine and coloring matters of the bile exert no such effect. They explain this, however, by assuming that the acids exert a direct paralyzing influence upon the cardiac muscle, while Röhrig attributes it to the destructive effect exerted by the bile upon the red blood-corpuscles.

Some interesting experiments, conducted by Dr. Francesco Spallitta, in the Physiological Laboratory of the University of Palermo (*Archivio per le Scienze Mediche*, vol. xi., No. 5, 1887), seem, however, to lead to a different conclusion. He experimented upon hearts removed from the body and also upon salt frogs, in order to eliminate the effect of the bile upon the red corpuscles. He used bile taken from different species of animals, and also experimented separately with glycocholic and taurocholic acids, but always obtained the same results.

We need not enter into the details of the experiments, which those interested will find fully described in the journal above referred to, but will give the conclusions at which the author arrived as a result of his investigations. He found that the slowing of the heart's action could not be due, entirely at least, to the loss of muscular power following upon the destruction of the red blood-

globules, since there was no blood present in the experiments made. It was therefore due to the paralyzing effect of the biliary acids acting directly upon the heart. But he showed that this was not the result of a direct action upon the cardiac muscular tissue, since other muscles, when impregnated with the bile acids, responded readily to electrical stimulation. Excluding, therefore, the destructive action upon the blood-globules and any immediate paralysis of the cardiac muscle as efficient factors in the production of this phenomenon, he came to the conclusion that the slowing of the heart's movements was due to an inhibitory effect upon the ganglia of the heart itself and upon the nervous filaments within the cardiac muscle. A similar action upon the central nervous system was, of course, excluded by the fact that the heart was removed from the body, and therefore its nervous connections were severed.

THE TREATMENT OF FUNCTIONAL GASTRO-ECTASIS.

Dilatation of the stomach is a disorder which French writers assure us is far more common and more often at the bottom of dyspeptic symptoms than has been generally supposed. The studies of G. Sée, Mathieu, Bouchard, as well as of German investigators, have brought the matter very prominently to the attention of the profession. The classification of dilated stomachs made by Mathieu in a recent contribution to the subject, is as follows:

1. Dilatation from organic lesion of the pylorus and constriction of that orifice.

2. Dilatation from degeneration of the muscular fibres of the walls of the stomach.

3. Dilatation from atony, or general feebleness of the muscular system.

4. Dilatation due to muscular atony from imperfect innervation, such as occurs in neurasthenia. Here there is at first an alternation of atony, with exacerbations of a hyperexcitability of the gastric muscle causing painful dyspepsia. Later there is permanent atonic dilatation.

It is only in the treatment of the last two classes of cases that much can be expected. Dr. Mathieu, in *Le Progrès Médical*, of February 12th, devotes an article to presenting the plan which he has adopted, and which is as follows:

First, as to diet. The stomach must never be overloaded, and consequently the number of meals should be increased and the amount taken at each lessened. All foods which leave a large residue of undigested matter should be forbidden, such, for example, as string-beans, salads, fruits; indeed, nearly all vegetables may have to be cut off except potatoes. The food ought to be very finely divided and thoroughly masticated. Wine should not be taken, as a rule. It is often better to have the liquids warm.

Second, the bowels must be kept carefully regulated. Almost all *les dilatés* are constipated. Professor Sée recommends for this condition a powder composed of sulphur, cream of tartar, and magnesia. A teaspoonful of this is taken at the beginning of each meal. Or enemata containing glycerine may be given each morning.

A third indication is to improve the general tone of the system. For this Mathieu thinks there is nothing better than a cold douche to the spinal column. In delicate patients the water may be at first warm.

The fourth indication is to strengthen in particular the muscular walls of the stomach. Calabar bean and nux vomica have been recommended for this purpose, but Dr. Mathieu thinks that there is nothing that begins in efficiency with powdered ipecac.

The prescription given is: ℞. Pulv. ipecac., ʒ ss; aquæ, ℥ v.; syrup. aurant. cort., ℥ v. M. Sig.: ʒ j. or ʒ ij. every two or three mornings. This is not a very agreeable mixture, however, and a better way is to give the powder in the form of wafers, each containing from four to eight or ten grains. The patient takes one of these every second or third day. Most persons are not affected by the larger dose, but in the more sensitive it may cause nausea and vomiting.

Fifth, the symptomatic treatment of the pressure-feelings, pains, distention, etc., which are noted in the neurasthennic *dilatés* is best accomplished with cocaine or chloroform water.

It will be seen that Dr. Mathieu's treatment of gastric dilatation is one that will apply very well to quite a large number of cases of dyspepsia, whether there is dilatation or not. We are ourselves somewhat skeptical as to the frequency of functional gastro-ectasis, and certainly it is not always easy to make out milder forms of this condition during life.

ARTERIO-SCLEROSIS AND THE FIBROUS DIATHESIS.

Dr. Isnard, of Marseilles, in a monograph recently published at Paris, presents the results of a study of generalized sclerosis and its relation to arterial sclerosis. He has made some special observations in this line, and draws from them the conclusion that we must add to our list of "diatheses" the fibrous.

He accepts the facts so well established by many investigators regarding the existence of arterio-sclerosis. He finds in addition that this arterial sclerosis begins in the inner coat of the arteries, which are in contact with the vitiated blood. Sclerosis is found developing in the same way in the veins and lymphatics. The next proposition is that the arteries are the point of departure of all the scleroses. Some particular dyscrasia, like alcoholism or syphilis, may provoke the new connective-tissue growth in one particular organ, like the liver or kidney, but in all cases the new growth radiates from the sanguineous canals.

The fibrous diathesis expresses itself, therefore, first in a generalized arterial or vascular sclerosis, with later and consequent visceral scleroses, involving lungs, liver, kidneys, spinal cord, according to the dyscrasia or the local irritant.

A further deduction is that the blood is at the bottom of the trouble in all these sclerotic disorders, since they start from the coats immediately bathed by it.

There are several European pathologists of some prominence who have advocated the vascular origin of sclerosis, but the view that such is always the history of this change is by no means generally accepted; indeed, by many it is considered definitely refuted.

In making sclerosis in general a disease due to a vicious condition of the blood, Dr. Isnard, of Marseilles,

comes very close to the view, as we have been told it, of a well-known pseudo-scientist of this city. The latter gentleman treats the "fibrous diathesis" by ridding the blood of the "spores," etc., which generate the morbid organic changes.

AN UNJUST JUDGE.

If we are correctly informed, an act of the grossest injustice was perpetrated by one of our city's judicial luminaries very recently. A reputable physician of this city, a graduate of the College of Physicians and Surgeons, was charged with assaulting a woman in his office. The woman in question went to some unknown and apparently illiterate practitioner, who examined her, and in barely intelligible English certified that she had a perforated hymen and an inflammation of the vagina, and that the perforated hymen had existed before the alleged assault! Yet, with nothing but this certificate and the assertions of the girl, the doctor was thrown into prison, and, being unable to raise the very large bail, had to remain there for several days.

We have seen the alleged certificate upon which the doctor was sent to jail, and it appears to us, as it must to everyone who has intelligence and a sense of justice, that the proceeding was a most flagrant outrage. Certainly there should be some remedy against the imbecility of uneducated judges who lend themselves so readily to what has every evidence of being purely a blackmailing scheme.

News of the Week.

Professor Henry I. Bowditch, in an address on Homœopathy at the annual meeting of the Rhode Island Medical Society, concluded with the following recommendations: "1. Let every State society follow the lead of New York, and let the members be *allowed*, without injury to their status in these bodies, to consult with members of other 'legally constituted' medical societies. 2. Let members of either of these sects join our State societies, provided they prove to the State examiners or censors that they have studied medicine a proper length of time, and are able to pass the examination required of all applicants for admission; and provided, moreover, they agree to cease to call themselves by any peculiar name because they desire to enroll themselves as members of our time-honored profession. 3. Let us endeavor to make the American Medical Association rescind the vote whereby it expelled the New York State Medical Society, simply because, by its resolutions, it intimated that the fight between the regular profession and homœopathy had lasted long enough, and that hereafter consultations would be allowed to all 'legalized medical bodies.' 4. As interweaved and intimately connected with this controversy, let us, on all proper occasions, by all means in our power, endeavor to induce the American Medical Association to annul the illegal action of the Judicial Council requiring an annual signature by all the members to its so-called Code of Ethics, under the penalty of not being allowed to attend and take part in the friendly intercourse and scientific discussions of its meetings, a measure which tends to keep alive our divisions and encroaches upon our individual rights of conscience, instead of promoting that harmony in the profession of America which the Association, by its great power for good, might bring about at these annual meetings in various parts of the country."

Dr. H. M. Silver has been appointed one of the Visiting Surgeons to Gouverneur Hospital.

The Columbus Medical Colleges.—Starling Medical College recently graduated a class of twenty-one, and the Columbus Medical College a class of eighteen.

Failure of Medical Legislation in Ohio.—The Sinnett Bill to regulate the practice of Medicine passed the Senate, but was killed in the House. The *Columbus Medical Journal* says: "The newspapers of the entire State were generally opposed to the bill, but chiefly from ignorance of its provisions. Several, however, fought it from, apparently, pure cussedness. The *Ohio State Journal*, of this city, was most conspicuous for its opposition. It freely admitted to its columns anonymous communications from the lowest quacks, and when there was a dearth of these, copied similar matter extensively from other papers, while its editorial columns teemed with the most absurd and contradictory statements concerning the nature of the bill. At the same time it steadily refused to admit any communication whatever in defence or explanation of the bill, or even in correction of its own outrageous untruths.'

The Nashville Medical News is the title of a new journal, published semi-monthly at Nashville, Tenn., and edited by Drs. Richard Douglas and John W. McAlister.

Sick Immigrants.—In 1886, 300,887 immigrants landed at Castle Garden, being 30,748 more than the previous year. Among them were about eighty thousand women, fifty-five thousand men, and children. Of the total, there were sent back 997. Of this number, 70 were insane, 20 were idiotic, 1 was blind, 88 were enciente, 8 were convicts, and 18 were cripples. Three hundred and fifty-five suffered from diseases which prevented them from earning a livelihood, and 437 were without means of support. As a result of an investigation into the management of the emigrant hospitals the committee reports: "Your committee are glad to be able to say that no charge of unprofessional conduct or misconduct on the part of any of the physicians of Ward's Island has been sustained on investigation, and it is hoped that the medical staff will continue to maintain the excellent character and *esprit de corps* which this investigation has shown it now possesses."

The Louisiana State Medical Society meets at Alexandria on April 11th.

The Prescriptions of European Physicians.—There is another peculiarity about the prescriptions of most continental physicians that is perhaps worthy of note, and that is, that they scarcely ever combine two remedies in the same recipe, or even give the patient two active remedies at the same time. Arterial sedatives, such as aconite, veratrum viride, and the like, so commonly prescribed with us, I have never heard even mentioned, much less prescribed, during my present stay in Europe.—Dr. Caldwell, in *Chicago Medical Journal*.

Jefferson Davis at a Medical College Commencement.—At the last Annual Commencement of the Medical Department of Tulane University, New Orleans, Jefferson Davis was present, and was the recipient of some baskets of flowers. In responding to the present he said: "I thank you from my heart for the kind courtesy extended to me on this occasion. May your paths in life be as flowery as these baskets, and may you illustrate in your careers the high principles that belong to your profession. Standing next to the ministry, you have not only the care of the body, but you are the repositories of family confidences. To you are intrusted secrets that none others know. You stand by the bedside of the dying and hear their last utterances. I trust that science, benevolence, and morality will go hand in hand in your profession."

Jefferson Medical College graduated a class of 187 at its Annual Commencement on April 5th.

Physicians and Lady Physicians Abroad.—Dr. W. S. Caldwell, writing from Paris to the *Chicago Medical Journal*, says: "Most American physicians whom one meets here are young men just from the colleges, and they are too often only interested in such cases as a man would see only occasionally in a lifetime. They are eager to see Billroth resect the pylorus for cancer, and are constantly presenting their cards to Péan to get a chance to see operations that they never ought to attempt to perform. But I am even more disgusted with some of the lady physicians who come here to Paris. They will be pushed and jostled amid the great throng that follow the surgical service of Gillan at the Hotel Dieu; sit on a back seat with an opera-glass in hand to see Péan amputate a man's leg at the hip-joint; but go to the Children's Hospital, where Simon holds his clinic, and one finds not a single one of them there."

Coffee contains from 1.18 to 1.28 per cent. of caffeine, the amount varying very little.—*Amer. Journ. of Pharm.*

Professors of the First Class in the Paris faculty receive $3,000 a year as salary. This is probably not much more than half what professors of the first class receive in our large colleges.

The Medical Society of the State of California meets at San Francisco on April 20th, 21st, and 22d. The society now has a membership of three hundred and thirty-eight, and is in a very prosperous condition.

A Small Operation with a Large Name.—"Porotomy" is the name given the operation of cutting the meatus.

The Ladies' Health Protective Association of this city has now six hundred members, having increased from seventeen members in two years. Its work this year will be devoted principally to tenement-houses and street-cleaning.

The Difficulty of Disinfecting the Alimentary Tract.—Furbringer has recently shown that the number of micro-organisms per cubic millimetre in the fæces of typhoid-fever patients who are taking naphthalin is ninety thousand. Other antiseptics appear equally unequal to the task of really disinfecting the intestinal contents.

The South Carolina State Medical Association held its annual meeting at Aiken on April 12th.

Talmudic Medicine. — Regarding the proposal to publish a work on this subject, a correspondent writes us that there already exists such a work in French. It is entitled "La Médicine du Talmud," and is, we are informed, pretty poor reading.

The Mississippi State Medical Society meets at Jackson on April 12th. An interesting programme of work has been prepared.

Sir Spencer Wells has gone to the Canary Islands for his health.

Two Misused Words, according to Dr. Sankey, are prodroma (of which the plural, often used, is prodromata), and calvarium. The Greek and the Latin word is *prodromus;* plural, *prodromi* (Dunglison, Webster). Calvaria is a feminine noun; plural, calvariæ.

Salicylate of Lithia.—Dr. Vulpian states that salicylate of lithia is more efficacious than salicylate of soda in cases of acute and progressive subacute articular rheumatism. It also has some effect in chronic cases when a certain number of the joints are still deformed, swollen, and painful. Four to four and a half grammes, and even five grammes, may be given in a day. If the improvement is not lasting, fifty centigrammes may be added to the daily dose. Sometimes, when the dose is increased to five or five and a half grammes, symptoms of intolerance begin to be shown. Salicylate of lithia may be given dissolved in water, in powder, or in unleavened bread, during or after meals, in doses of fifty centigrammes. The physiological effects of the drug are headache, giddiness, and deafness.—*British Medical Journal.*

The Townsend Pavilion.—The corner-stone of the new surgical pavilion for laparotomy, at Bellevue Hospital, was laid on April 11th, with appropriate ceremonies.

The Vassar Brothers' Hospital, at Poughkeepsie, was opened for visitors on the 11th. It contains forty beds. The property is valued at $125,000, and has an endowment of $300,000. Dr. Guy C. Bayley is resident physician.

Swallowing Artificial Teeth.—A correspondent of the *British Medical Journal* reports a case in which the patient swallowed a plate with artificial teeth, and safely passed them *per rectum* a few days later. Another correspondent says: "A patient of mine recently swallowed a plate (gold, with two teeth), and I immediately adopted a practice recommended to me some years ago by Sir James Paget in a similar case. I made him eat three good-sized slices of bread, and swallow four tablespoonfuls of flour and water made into a fairly thick mass. I then administered an emetic, and the teeth returned entangled in the tenacious vomit. I may add that the first case was equally successful, and that something of this sort is habitually done at police-stations when prisoners arrested for passing false coins swallow them."

A Pseudo-Atrophy of the Optic Nerve is said to exist, by Dr. Trousseau, of Paris. It is due to toxic influence, and is diagnosticated from true atrophy by the use of pilocarpin.

An Official Decision regarding the Printing of the Title "Doctor" on United States stamped envelopes, postals, etc., has recently been rendered. A physician of this city ordered one thousand stamped envelopes printed with the prefix "Dr." before his name. The New York Post Office refused to allow the prefix to be used, holding that it advertised his calling. On appeal to the Washington authorities the decision was overruled, and the doctor was allowed to have his envelopes printed as he desired. The decision is manifestly the just and correct one, and we are glad to place it upon record.

The Fourth Annual Meeting of the American Climatological Association will be held in Baltimore, Tuesday and Wednesday, May 31 and June 1, 1887, and will immediately precede the meeting of the Association of American Physicians, to be held in Washington.

Memorial to the Late Surgeon Ambler, U.S.N.—The medical officers of the navy have just had completed a beautiful tablet in bronze, commemorative of the heroism of Surgeon J. M. Ambler, who perished with De Long and his companions in the Lena Delta in 1881.

At the Commencement of the Buffalo Medical College the degree of M.D. was conferred upon a class of fifty.

Reviews and Notices of Books.

Principles of Hygiene for the School and the Home. By Ezra M. Hunt, A.M., M.D. Pp. 377. New York and Chicago: Ivison, Blakeman, Taylor & Co. 1886.

The writer has had no easy task to write upon hygiene in such a manner as to bring it within the comprehension of school-children. At the same time he conscientiously sets himself about the still more difficult task, that of bringing to the knowledge of his pupils enough of the anatomy and physiology, which forms the basis of human hygiene, to make it comprehensible to them. To say that he has been successful is to award him great praise, but he deserves it, since he has presented his subject scientifically, clearly, and simply.

A Manual of Obstetrics. By A. F. A. King, A.M., M.D. Pp. 379. Philadelphia: Lea Brothers & Co. 1886.

The fact of a third edition of this work shows that it is appreciated by students, who regard it as helpful in fixing the aphorisms of obstetrics for examination and for future use.

On Fevers: Their History, Etiology, Diagnosis, Prognosis, and Treatment. By Alexander Collie, M.D., Aberdeen. Pp. 288. Philadelphia: P. Blakiston, Son & Co. 1887.

The author of this little volume writes clearly, concisely, and authoritatively upon the subject of fevers, as is the right of one who can state in the preface that his observations for the most part are founded upon over twenty-one thousand cases which he has personally treated from commencement to termination. The plates of the lesions of the enteric bowel and the eruption of variola nigra are creditable specimens of medical illustration, and show a great advance in this line of work.

Transactions of the American Surgical Association. Vol. IV. 1886.

Among the number of valuable papers presented in the present volume, the most able, scientific, and in a manner most valuable, is Dr. Lerna's contribution to the subject of "The Surgery of the Pancreas." Prefaced with a study of the embryological development of the pancreas, there follows a discussion of its anatomical and pathological structure, with a working up of its physiological functions, illustrated with elaborate experiments on animals; the paper concludes with a review of the diseased conditions of that organ and a report of the cases in which surgery has been employed, and the results of the same. The whole forms a remarkable monograph in this new and almost unexplored surgical field.

The opening address by the president, Dr. Moses Gunn, on the "Union of Nerves of Different Functions," is also extremely interesting. In it he proves that the function of a given nerve depends entirely upon the machinery at its end, and not upon any intrinsic quality.

Dr. Johnston's paper on "Diagnostitial Laparotomy" recommends that the operation should be more extensively employed in obscure cases, especially intestinal cases, in which life might sometimes be saved by it.

A valuable contribution to science is the paper on the "Bacteria of Surgical Diseases," by Dr. Harold C. Ernst, of Harvard.

A Compend of Electricity, and its Medical and Surgical Uses. By Charles F. Mason, M.D. Pp. 108. Philadelphia: P. Blakiston, Son & Co. 1877.

This forms the third volume in the series published by the above firm under the title of "Medical Briefs." The statements of the uses of electricity and all of the definitions are given in the most succinct manner. In fact, in some instances lucidity is sacrificed to brevity, and it is doubtful if one who had recourse to no other authority would get on very well in all of the practical applications of electricity without further directions than are given in this book.

Massage as a Mode of Treatment. By William Murrell, M.D., F.R.C.P., Lecturer on Pharmacology and Therapeutics at the Westminster Hospital; Examiner in Materia Medica in the University of Edinburgh, and to the Royal College of Physicians of London. Second edition. London: H. K. Lewis. 1887.

We noticed the first edition of this instructive little treatise a few months ago, and the fact that a second edition has been so soon called for is an evidence of the favor with which the book has been received. The work has been largely rewritten for this edition, and many cases recently under the author's observation have been added.

The Truth about Alcohol. By Robert Alexander Gunn, M.D. Chicago and New York: Belford, Clark & Co. 1887.

In this little book the author discourses pleasantly about alcohol, its uses and abuses. It would be an excellent tract for prohibitionists to read, and would perhaps have the effect of inclining them to look with a little charity on those who do not hold in every minute point to their own extreme views.

Physician's Clinical Case and Record Book. San Francisco: William S. Duncombe & Co. 1887.

A printed list of symptoms and attributes of a patient to be examined is a very great aid in systematic case-taking. It is especially valuable to a physician just learning the art, for he is sure to find, without such assistance, that he has forgotten to inquire about some region of the body or to bring out some symptoms which are essential to the proper understanding of the case. The Clinical Note-Book will thus be found very useful.

THE SCIENCE AND PRACTICE OF SURGERY. By FREDERICK JAMES GALT. Vols. II. London: Published by Baillière, Tindall & Cox. 1886.

THE third edition of Gaut's Surgery comes to us, revised and enlarged, with more than two thousand pages and one thousand and ninety illustrations. The writer has been able to treat his subject in the most exhaustive manner. It is topographically very fine. If any criticism were to be given, it might be relative to the style, which is somewhat discursive. For example, in speaking of erysipelas, he announces, "any *repressive* application would be obnoxious; not only as tending to divert the natural course of the disease in the elimination of the blood-poison, but as possibly repelling the inflammation to some other part, its migration or metastasis being perilous and prolonging the disease. In both these respects the cutaneous inflammation of erysipelas is analogous to an attack of gout." This paragraph is one of a number selected at random. It is only a writer who has two thousand closely printed pages to hold his ideas that can allow his pen such garrulity; the other factor to be considered is the patience of the reader. The two being equal, the result is a success.

CONGRÈS PÉRIODIQUE INTERNATIONAL DES SCIENCES MÉDICALES. Vols. IV. Copenhagen. 1886.

THE Eighth International Congress leaves its impression upon the medical world in the shape of four large volumes filled with the papers presented to this august body. The papers are published in French, English, and German, according to the mother tongue of the writer. Aside from the social enjoyment and the great gratification which arises from coming face to face with the foremost medical men of the age, men who have long made a wide circle of acquaintances by means of their erudite and scientific pens, the results of this Congress are crystallized before us in this *Compte-rendu*.

Many of the subjects, even in so short a time as since 1884, have been discussed and views modified; such is the case with the paper read by Pasteur on "Microbes pathogènes et Vaccins."

The Section on Anatomy contributes, perhaps, as little of general interest as any of the sections, many of the papers touching on minor points. As physiology differs from anatomy in still offering a wide field for experimental research, at such a meeting as this opportunity is afforded for giving the results of experimental investigation, and the student will turn to these with great profit and interest. The same is true of the work done in the Section of General Pathology. So each specialist will find that the knowledge of his department is amplified and increased by the many able papers contributed.

The whole large work impresses the reader with the benefit which accrues to the medical profession from this periodical interchange of national ideas, as well as the promotion of good feeling and the unity of interests and endeavors of those who practise the art of healing.

A TEXT-BOOK ON SURGERY: General, Operative, and Mechanical. By JOHN A. WYETH, M.D., Professor of Surgery in the New York Polyclinic; Surgeon to Mount Sinai Hospital; Consulting Surgeon to the Yorkville Dispensary and Hospital for Women and Children; to the Woman's Hospital of Brooklyn, etc. New York: D. Appleton and Co. 1887.

WE turned to this book with a feeling of weariness, for it seemed as though there were enough works on general surgery to satisfy the most ardent seeker after knowledge, or to instruct the most ignorant of would-be practitioners, but we confess that we were disappointed—very agreeably disappointed. The writer has succeeded in the very difficult task of creating a want, where no want was felt, and then of satisfying it. In a work of this kind, embracing the entire range of surgery, with the exception of operations on the eye, the author cannot, in seven hundred and sixty pages, discuss unsettled theories or compare methods, and he must necessarily be somewhat dogmatic. But this is compensated for by clearness of description and preciseness of language—qualities of essential importance in the writer of a text-book of this nature. The illustrations are numerous and excellent; and those in the section on Ligation of Arteries are worthy of special commendation. In those the arteries and veins are shown in colors, and each part is, when necessary, distinctly labelled in place, thus doing away with the ordinary figures or letters, with the references in the text, which are better calculated to confuse than to aid the reader in his comprehension of the cut. We are sorry to see that the author has followed the too prevalent custom of adding to his name a string of titles, some fifteen or more in number, having, for the most part, little or no bearing upon his qualifications as a teacher of surgery. An author's work speaks for him, and it adds nothing to his estimation in the minds of his readers to inform them, on the title-page, that he is a member of the New York County Medical Society, or an honorary member of the College of Physicians and Surgeons of Little Rock. This is, however, our only criticism, and, of course, detracts in no way from the intrinsic value of the work, which is of superior merit, and which no one who is ever called upon to treat surgical cases can well afford to be without.

THE PRINCIPLES AND PRACTICE OF OPERATIVE SURGERY. By STEPHEN SMITH, A.M., M.D., Professor of Clinical Surgery in the University of the City of New York; Surgeon to the Bellevue and St. Vincent Hospitals, New York; Consulting Surgeon to St. Elizabeth's Hospital, etc. New and thoroughly revised edition. 8vo, pp. 877. Philadelphia: Lea Brothers & Co. 1887.

A BOOK which is fully in harmony with the spirit of the times, and one which will be appreciated at a glance by every practical surgeon. Those who are engaged in other lines of medical work can refer to it with great advantage, in order to learn what surgeons are doing nowadays. Its sharply defined lines of description make it a very easy book to read, and the author's plan of quoting the names of authorities in the margin only, and including their ideas in an unbroken text, will avert interruption and confusion.

The author, in a chapter devoted to the subject, shows just why the surgeon is under obligations to practise surgery according to actual antiseptic methods, and we presume that the law courts will make this a book of reference in malpractice cases in which patients have not received the attention which is now demanded of operators. Consequently a study of the work will be profitable in more ways than one.

The details of antiseptic surgery, as practised at three of the most progressive centres of the world—Billroth's Clinic, Lister and Cheyne's Clinic, and Bellevue Hospital—are described in such a way as to make the matter a most valuable feature of the work. The busy general practitioner and the student will appreciate the brief completeness of the author's style.

The surgery of the brain and of the abdomen is advanced in the work to the farthest point recognized by the best authorities at the present date, and we can say with confidence that Professor Smith's practical arrangement of points will do much to throw into disrepute the unfortunate plan of treating so many wounds of the brain by the expectant method.

All of the subjects which interest the general surgeon are handled in a way which would be expected of the author, and his adaptation of recent scientific points in the breezily progressive surgery of to-day is highly satisfactory.

The volume is a handsome one as to type, paper, illustrations, etc., but is nevertheless not expensive. It contains upward of two hundred more pages and illustrations than the former edition.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, February 23, 1887.

T. Mitchell Prudden, M.D., President, in the Chair.

THE REPORT FROM THE COMMITTEE ON MICROSCOPY,

on the uterus and its appendages presented by Dr. H. J. Boldt at the last stated meeting, was submitted, as follows:

Sections were made from one of the retro-peritoneal glands. Its perivascular spaces were found to be irregularly dilated, and packed full of irregularly shaped epithelial cells. The epithelial cells within the alveolar spaces were not separated by any intercellular substance, and they had no definite arrangement. Between the masses of cells the fibrillated connective tissue was increased in thickness, and infiltrated with new cells. Carcinoma.

G. C. Freeborn,
William H. Porter.

ACUTE ANTHRACOTIC PNEUMONIA.

Dr. William H. Porter presented sections made from the lungs removed from a case of acute anthracotic pneumonia, with the following report:

Upon microscopical examination, the interlobular connective tissue was found to be very much thickened and in a state of œdematous infiltration. This thickened tissue was also infiltrated with inflammatory cells, also small and large round connective-tissue corpuscles. That this very apparent interstitial thickening was chiefly œdematous in character was proved by its rapid decrease in passing the sections through the absolute alcohol.

The air-vesicles were filled with the ordinary inflammatory exudation common to lobar pneumonia, the larger portion of which was in the stage of gray hepatization, but a few of the air-vesicles still contained a delicate reticulated net-work of fibrillated fibrin.

The most interesting point was the very large amount of black and apparently inorganic pigment which was found in large quantities in the inflammatory exudation into the air-cells, while the interstitial tissue contained comparatively little.

No pneumococci could be found. In these cases both the interstitial and intravesicular inflammation apparently was due to the large amount of inorganic pigment drawn into the lungs. In these particular instances the evidence is strongly against an infection or germ as the cause of the pneumonic process, and most decidedly favors a direct injury as the causative agent.

PISTOL-SHOT WOUND OF THE BRAIN.

Dr. Porter presented a second specimen, with the following history: Male, twenty-three years of age, German, who had been to a ball the night before. He returned early in the morning, and shot himself without apparent cause. Death followed in about two hours from hemorrhage.

At the necropsy the track of the ball was found to be from right to left completely through the skull. The direction was such that both right and left middle meningeal arteries were divided. The bullet-holes in the bony walls were about three-eighths of an inch in diameter, while that through the brain-substance was about one inch in its diameter. The course of the ball through the brain was from right to left, just in front of and below the lateral ventricles. There was a stellate fracture at the vertix, and both orbital plates were fractured; also the occipital bone on both sides of the foramen magnum. The special points of interest were the complete division of the middle meningeal artery upon both sides; the small bullet-hole in the skull, and its large diameter through the brain-substance; the slight amount of intracranial hemorrhage, and the large number of cranial fractures.

TRICUSPID AND BICUSPID INSUFFICIENCY—AORTIC STENOSIS — CARDIAC DEFORMITY — INTERSTITIAL PNEUMONIA—AND INTRALOBULAR CIRRHOSIS OF THE LIVER.

Dr. Porter presented a third specimen, with the following history by Dr. William A. Moore, house physician:

C. R. H——, twenty-four years of age, was first admitted to the service of Dr. A. H. Smith, at the Presbyterian Hospital, January 8, 1887, and later to the service of Dr. William G. Thompson. He gave a family history of both phthisis and cardiac disease. He has had repeated and severe attacks of rheumatism; the last, which was unusually severe, occurred five years ago. He has also had pleurisy and typhoid fever. For a number of years he has suffered with dyspnœa and cardiac trouble. The present sickness commenced December 19, 1886, as a severe cold. When admitted he was very anæmic and considerably emaciated. His feet and legs were œdematous.

Physical examination revealed a dilated, a rapid and tumultuous heart's action, and a widely diffused apex-beat. Upon auscultation a distinct bicuspid and tricuspid regurgitant murmur was heard; also a slight aortic obstructive murmur. There was marked jugular pulsation.

The patient gradually sank, and died from exhaustion and cardiac failure.

Necropsy twenty-four hours after death. Body very much emaciated; rigor mortis marked.

Thoracic cavity: The pericardial sac was completely obliterated by an old and fibrous pericarditis.

The left auricle was dilated and its walls very much thickened. The endocardium looked like dense white, fibrillated connective tissue. One segment of the mitral valve was shortened and bound down to the ventricular wall. The opposing segment was elongated and thickened.

The left ventricle was about normal in size, but its muscular wall was thin and degenerated. The segments of the aortic valve were the seat of numerous small vegetations. The aorta was the seat of extensive endarteritis and fatty infiltration.

The cavity of the right ventricle appeared to be very much diminished in size; the segments of the tricuspid valve shortened and adherent to the cardiac wall, thus nearly obliterating their usefulness. The right auricle was very much dilated, its endocardium in a state of fibroid thickening similar to that of the left auricle. The muscular coat was greatly thickened and reticulated. Both lungs were firmly bound to the chest-wall by old pleuritic adhesions. There was a marked interstitial thickening, some congestion and œdema of the pulmonary substance, also a few zones of broncho-pneumonia.

Abdominal cavity: The *spleen* was normal in size. Its capsule was thickened by fibrous patches. The *kidneys* were the seat of a moderate amount of chronic diffuse nephritis. Their pelves were the seat of punctate hemorrhages and were deeply congested. Weight of each six ounces.

The *liver* was enlarged, weighing sixty ounces. Its external surface was covered with patches of fibrillated connective tissues, and fringes of the same hung from its external surface in many places. There was a marked intralobular cirrhosis, and numerous microscopic gummy formations in the intralobular spaces.

The chief points of interest are those in connection with the heart, viz., extensive lesions upon the right side are very uncommon. Out of two thousand necropsies only two have given evidence of primary changes on the right side. As a late secondary lesion to organic valvular changes on the left side, a degeneration and dilatation

of the right ventricle causes both pulmonary and tricuspid insufficiency. But organic changes causing valvular lesions of the right side are extremely rare. From the almost universal absence of any organic valvular change in the pulmonary and tricuspid valves, and from the well-known physiological fact that the tricuspid valves are always insufficient, we can, practically speaking, exclude valvular lesions of the right side of the heart when making a physical examination of the heart.

MULTIPLE AND RETAINED GALL-STONES—PARENCHYMATOUS METAMORPHOSIS OF THE LIVER AND KIDNEYS—MARKED JAUNDICE.

Dr. Porter presented a fourth specimen, with the following history abstracted from the very complete one taken by Dr. William A. Moore, house physician: Mrs. M. F——, aged thirty-two, Irish, laundress, was admitted to the service of Dr. William G. Thompson at the Presbyterian Hospital. There was a clear history of repeated attacks of biliary colic and severe facial neuralgias, otherwise her previous history was good. Her present attack commenced on February 1, 1887, with a severe pain in the right side, and the next day she commenced to menstruate. The pain continued, but was intermittent in intensity. Two days before entering the hospital she had a severe chill, followed by a high fever.

February 12th she was admitted, and was found upon examination to be a large and very fleshy woman, the skin had an ashy hue, and she had every appearance of being a very sick person. The conjunctivæ slightly jaundiced; none of integument. Physical examination negative.

She remained in the hospital until February 21st, with symptoms which pointed toward occlusion of the common bile-duct, such as biliary colic, progressive jaundice, clay-colored stools, and high-colored urine. There were frequently repeated chills. The temperature ranged between 100° F. and 107° F., but most of the time it was above 103° F. It rose after each chill, but would fall for a time after thirty grains of antipyrin were taken.

General sponging of the body kept the temperature more evenly down.

On the 17th exploratory aspiration of the hepatic region, but no pus was obtained.

On the 19th albumen appeared in the urine, followed the next day by casts. The amount of urine voided was fair in quantity. Stimulants were freely administered, but all the symptoms grew worse. Her mental faculties remained clear to last, but heart gradually failed, and death appeared to be due to uræmic poisoning, œdema of the lungs, and cardiac paralysis.

Necropsy twelve hours after death. Rigor mortis marked. Body deeply stained yellow, as were all the tissues. Adipose tissue abundant. Thoracic cavity: The pericardial contained one-half ounce of yellow, serous fluid. The heart was soft, flabby, and its cavities dilated; weight twelve ounces; valves normal. Microscopically the muscular fibres were found to be in an advancing state of granular metamorphosis. The left lung was slightly adherent to the chest-wall, but there was no fluid in its pleural cavity; weight eighteen ounces. The right lung was slightly bound to the chest-wall at its apex by old adhesions. At the ninth intercostal space, about midway between the axillary and anterior scapular line, there was a marked patch of punctate subserous ecchymosis, with a slight amount of blood-stained fibro-plastic exudation. The same condition was noticed in the pulmonary and diaphragmatic pleura. There were a few ounces of blood-tinged serum in the right pleural cavity; weight of right lung eighteen ounces. Both lungs were congested and œdematous. Abdominal cavity: The peritoneal cavity contained about one pint of fluid blood and about the same amount of blood-clot. This firm clot lay between the liver and the posterior abdominal wall. There was also considerable retro-peritoneal hemorrhage. There was no peritoneal inflammation. The spleen was large and soft; weight ten ounces. Kidneys: Both glands were very much enlarged and softened; their capsules non-adherent. The cortex was thickened, the markings straight. Upon microscopic examination the epithelium was found to be in an advancing stage of granular metamorphosis. There was no evidence of an inflammatory action, but there was considerable bile-pigmentation. There was a granular condition of the os uteri, also an inflammation of cervix and fundus uteri. There was cystic degeneration of both ovaries, also a pedunculated fibroid of the fundus, one inch in diameter; alimentary tract normal. The duodenum was opened in situ, and the common bile-duct found to be patent, but just within its orifice it was widely dilated. All the hepatic tributaries were dilated, and contained small gall-stones. The gall-bladder was thickened and punctated. The gall-bladder and the hepatic tributaries contained in all eighty-six gall-stones, ranging in size from one eighth of an inch to one inch or more in diameter. The liver showed marked parenchymatous change and granular metamorphosis, but no positive inflammatory or suppurating foci.

EXSECTION OF THE HEAD OF THE FEMUR.

Dr. L. H. Sayre presented the head of the femur and a portion of the acetabulum removed from a boy thirteen years of age. The operation was performed February 21, 1887. The family history of the patient was good, and he had always enjoyed a fair degree of health. It had been noticed, however, that all through his life he had walked with a peculiar movement about the hip, and, as described by his sister, "as if he had a wooden leg."

Three years ago he had a severe fall, striking upon his right hip, and two years ago his lameness had become so marked that he was sent to a surgeon on account of supposed morbus coxarius. After examination it was concluded by the surgeon that the case was one of reflex trouble, and the patient was circumcised. The improvement after the operation was very pronounced, and for eighteen months the boy walked about as he had always done before receiving the fall.

On last Thanksgiving Day, after exposure, he complained of slight pain in the hip, became somewhat languid, and at the end of six weeks a marked deformity was present, yet it differed from that seen in the third stage of hip-joint disease. The leg was slightly flexed upon the thigh and the limb was adducted across the middle third of the opposite thigh, but the foot was not rotated inward. There was slight tenderness on pressing the head of the femur into the acetabulum, but no tenderness on pressing the bone upward. There was slight motion at the joint, but it was apparently nearly anchylosed. The entire buttock on the right side was enlarged and indurated. At no time had the boy suffered from the pain usually associated with hip disease.

The diagnosis was probable

OSTITIS OF THE ILIUM, INVOLVING THE ACETABULUM;

the condition of the head of the femur was not made out satisfactorily. The patient was put to bed and made more comfortable by the adjustment of an extension apparatus.

About two weeks ago Dr. Sayre detected deep-seated fluctuation over the gluteal region. The patient had then begun to lose his appetite and to have irregular chills. Dr. Sayre then made an exploratory incision, and found an abscess from which he evacuated four or five ounces of pus, which was without débris and did not present the appearance usually shown by pus associated with dead bone. The capsule of the joint was ruptured, and, under anæsthesia, the movements of the joint were quite free.

At this stage of the operation it became a grave question whether to simply drain the abscess or to explore concerning the condition of head of the femur and, if necessary, perform exsection.

On manipulation, however, a small quantity of the

peculiar gelatiniform material seen with chronic bone-disease oozed from the ruptured capsule, and it was at once decided to exsect.

After the upper part of the femur was removed, it was found that the whole of the articular cartilage had been loosened from the head of the bone; and that the carious process had extended through the head of the femur entirely. The acetabulum was carious at the upper portion, and from about the insertion of the ligamentum teres he removed dead bone down to the internal periosteum, but did not enter the pelvis. The cavity of the abscess was cleaned out thoroughly, a drainage-tube was introduced, and the wound was closed. Since the operation the patient had been doing well; pulse, 100; and temperature, 99° F.

Dr. J. F. Ridlon cited a case which he saw first about five years ago, and in which recovery had taken place. He had been in the habit of treating these cases by other means than exsection, with the expectation of getting good results, hence he was specially interested in seeing the head of the femur removed at this stage of the disease. The symptoms, in his case, began with a little limp, following hemiplegic chorea, that continued without pain, tenderness, or reflex muscular spasm for nearly a year.

The case was watched very carefully by a competent orthopædic surgeon, and finally a traction-apparatus was applied. About one year and a half after the first symptoms were noticed, a small abscess was found in the gluteal region just below the great trochanter and behind, which gradually increased in size until it was as large as half a medium-sized orange, and then disappeared.

He mentioned the case for the sake of asking Dr. Sayre if he had seen abscess in the gluteal region except where there was perforation, as in his case, through the head of the bone rather than the capsule of the joint. His own belief was, and always had been, from clinical observation, that the abscess of hip-joint disease usually opened in front when it opened through the capsule, but when it opened through the bone the opening was outside of the capsular ligament, as in this case.

He would also inquire how long the abscess had existed when it opened. Four or five days ago he saw a case of hip-joint disease in which the abscess showed itself first in the anterior part of the thigh, one year ago last November. No apparatus was applied; the case was, substantially, let alone, and the abscess gradually increased in size until last Saturday, when it ruptured. At that time it occupied the upper third of the anterior portion of the thigh and the posterior part of the thigh to the extent of about half-way down to the gluteal region. It discharged only a very small quantity of pus, and on the following Monday fluctuation could not be made out. There had been no pain for a year and two or three months.

He regarded the absence of pain as of no importance at all in the early diagnosis of disease of the hip-joint. He believed that pain was one of the later symptoms of morbus coxarius.

Dr. Sayre said that the case had been under his observation about seven weeks. When he first saw it the entire gluteal region was enlarged and indurated, and fluctuation was detected about three weeks ago. He had seen cases of hip disease without pain, and he had been of the opinion that the disease began in the bone, rather than any of the other structures of the joint, and gave rise to extensive changes in the osseous tissue. He had seen a case like that mentioned by Dr. Ridlon, in which the abscess was apparently absorbed, and the reason why he operated in the present case was because the boy had marked constitutional symptoms. He had never exsected a joint in the condition shown by the specimen, and should look with great interest for the result of an early operation. The cases in which he had seen exsection had been those which were of many years' standing. According to his experience the abscess in hip disease almost always opened upon the thigh, either anteriorly or posteriorly.

ABSCESS OF THE LUNG SIMULATING EMPYEMA, IN A CHILD THREE MONTHS OLD.

Dr. L. Emmett Holt presented the lungs of a female child, in which the whole right lower lobe was converted into an abscess-sac with a thin wall.

The history was as follows: The child, an inmate of the New York Infant Asylum, was first seen on October 23, 1886, it having been ill three days with pulmonary symptoms. The temperature had varied between 102° and 103.5° F. There was cough and accelerated respiration. Physical examination showed exaggerated resonance and respiration over the left lung, with a few coarse râles. On the right side the râles were finer, the breathing in places broncho-vesicular, and over the whole lung behind there was a shade of dulness. It was noted as being questionable.

On the eighth day the temperature, which had remained uniformly at the height mentioned (102° to 103° F.), fell to 100° F., and for the week succeeding scarcely rose above 101° F. The examination of the lungs on the eighth day showed on the left side only exaggerated resonance and respiration. On the right side there was moderate dulness, back and front, with diminished respiratory murmur over the lower lobe, and bronchial breathing at the apex.

He did not see the child again until the seventeenth day, when the house physician called his attention again to the case, as the "broncho pneumonia" (this had been the diagnosis up to this time) was not clearing up well, and the temperature had risen to 102° F. again. The general condition was excellent, however; the child was plump and well nourished, nursed well, had only a moderate cough, slight looseness of the bowels, but no night-sweats. One would not have suspected from the facies and general appearance that anything ailed the child.

The physical signs found now were, flatness over the lower three-fourths of the right lung, front and back; this line of flatness varied also with position; there was absence of respiration over this part, and bronchial breathing at the apex. The apex-beat could not be made out to be displaced. An aspirator was introduced near the inferior angle of the right scapula, and, much to the surprise of all present, the effusion was found to be purulent. Nearly three ounces of healthy pus was evacuated; it was odorless.

Four days later, on the twenty-first day, the signs pointed to refilling of the chest, and the aspirator was again introduced, but only half an ounce of pus could be obtained.

The general symptoms were not specially changed during this interval; the temperature remained low until the twenty-fourth day, when it rose rapidly until it touched 105° F. Symptoms of great dyspnœa, cyanosis, and prostration developed, and the child died during the night. When these new symptoms developed, the house physician twice introduced the aspirator needle, but obtained no pus.

Autopsy.—Body well nourished; head not opened.

Thorax.—On removing the sternum, the left lung was found collapsed and compressed; the chest was nearly filled by the right lung, which extended two inches to the left of the sternum, overlapping and slightly displacing the heart. There were tolerably firm adhesions over the whole right lung, but no effusion whatever in the pleural cavity.

THE DIAPHRAGM WAS DISPLACED DOWNWARD.

On the lungs being removed, the right lower lobe was found greatly enlarged and had a fluctuating feel. On being incised, about three ounces of thick pus escaped. The lobe was hollowed out and consisted of little more than the wall of an abscess. Posteriorly the living tissue was thinnest, being scarcely two lines in thickness. At

no point was it much over one-fourth of an inch thick, except about the root of the lung. The inner surface of the sac was rough and irregular, and seemed to have no well-defined pyogenic membrane. The bronchi were carefully followed out, but no communication existed between any of them and the abscess. The right upper lobe was partly compressed and partly consolidated, some small patches of pneumonia being seen in its lower border. The left lung could be easily inflated, except at one or two patches of presumably old collapse. The bronchial glands were slightly enlarged, but not cheesy. The capacity of the abscess-sac was found to be about four ounces. The other organs showed nothing of importance—the heart was healthy; the intestines showed evidence of slight catarrhal inflammation; kidneys normal in size, slight cloudy swelling; liver somewhat fatty, not enlarged; spleen normal. No evidence of a suppurative process was found anywhere. The bronchi leading to the lobes of the right lung showed evidence of a slight catarrhal inflammation only. No foreign body was found, nor anything else to act as a local cause of the abscess.

The case, so far as the speaker's observation and reading went, was a very unique one, and the diagnosis made of broncho-pneumonia, followed by effusion into the pleura, seemed fully justified by the symptoms. It was difficult to see how the differential diagnosis between such an abscess and empyema could be made.

Dr. Frank Ferguson mentioned a case of abscess of the right lung, with a smooth limiting membrane, occurring in an adult. There was a granular condition of the pleural surface of the lung over the abscess, but not very extensive adhesion to the chest-wall, and the cavity had communicated with a bronchus which admitted a probe about one-tenth of an inch in diameter. He thought that it was primarily connected with this bronchus. The abscess was in the lower lobe, and in the upper lobe were numerous miliary tubercles.

Dr. Ferguson presented a specimen of

STRICTURE OF THE ŒSOPHAGUS,

occurring in a child two years and two months old, who was admitted into the New York Hospital on February 17, 1887. Her family history was good, and she was perfectly well up to three months prior to her admission, when she swallowed a small quantity of caustic potash.

Since then she had not been able to retain any food, but constantly vomited at every effort to eat or drink. Her appetite was very good; her bowels were constipated. On admission she was found extremly emaciated. Whatever was given her to eat or drink was retained only for a moment and then she passed her finger into her mouth and regurgitated what she had taken.

Auscultation revealed that the fluids and solids taken did not travel the entire length of the œsophagus.

The passage of a bougie was interrupted at about the middle of the tube. The child rejecting everything given her by the mouth, was put on nutritive and stimulating enemata, which she retained when given in small quantity.

During her residence in the hospital her temperature ranged below one hundred, and her condition was such that operation was not regarded as advisable. She died thirty-four hours after admission.

The *autopsy* revealed a stricture of the œsophagus, about its middle, two inches in length, and admitting a probe one-eighth of an inch in diameter. The œsophagus above the stricture was dilated; below it, normal. There was much thickening of the wall of the œsophagus in the neighborhood of the stricture.

The stomach was very anæmic, but otherwise normal. The other organs also were all anæmic, but otherwise normal. The body was greatly emaciated.

The Society then went into executive session.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN OBSTETRICS.

Stated Meeting, March 24, 1887.

E. L. Partridge, M.D., Chairman.

Dr. Hubbard W. Mitchell read a paper entitled

OPERATION FOR STELLATE AND BILATERAL LACERATION OF THE CERVIX UTERI,

in which he spoke of the frequency of the occurrence, of the injury, of its forms, of the difficulty of recognizing it at the time of labor, of the possibility of absence of after-symptoms and of spontaneous healing, of the symptoms to which it may give rise as mentioned by Thomas, of the liability to the occurrence of epithelioma in consequence, described by Emmet, and then proceeded to describe the method of operating which he had practised, after preparatory treatment, consisting of cleansing the parts, scraping away all granular material with the sharp curette, the use of hot-water injections, and applications of solution of nitrate of silver, forty grains to the ounce.

He uses his own speculum, a modification of Sims', which is a Sims blade with two broad, separate wings, bent into such a curve as holds up the upper labium (patient in the Sims position, profoundly anæsthetized) and depresses the lower labium, and gives a wide vaginal opening through which to work. It has one large, movable handle, that can be attached to blades of various sizes. Having located the place where the future os is to be, he cuts away all unsound tissue. The circular artery is almost invariably divided. He uses interrupted silver-wire sutures, five or six to the inch, and threads the wire directly into the eye of the needle. He removes the sutures on the tenth day. Of the 113 cases on which he had operated union by first intention took place in 110. Of the 65 cases of bilateral laceration, pregnancy occurred subsequently in 8, and at the next labors—he attended them all—laceration occurred in only one, and there it was only slight.

Dr. C. C. Lee said that he had been favorably impressed with the paper, which contained an excellent exposition of the present state of knowlege with regard to trachelorrhaphy, but that he should be obliged to differ with its author concerning some of the details of treatment. He thought that the

LOCAL APPLICATION OF NITRATE OF SILVER

did more harm than good; weak solutions of iodine were more beneficial. He had never seen a needle that could be managed so well as the carrying-loop, in using silver-wire sutures. It had not been his experience that the circular artery had been divided in the operation in a greater proportion than one in twenty cases, and when divided he had regarded it as an accident rather than an almost necessary part of the operation.

Dr. Wylie could not agree with the general import of the paper or find very much in it to commend. He believed that to speak of laceration of the cervix as a disease was calculated to do harm and increase the number of operations, judging from the very large number of patients operated upon in so short a time by Dr. Mitchell.

A perfectly healthy, normal cervix is not likely to be lacerated. But if the cervix is imperfectly developed, or has been the seat of disease, it is very liable to be lacerated, and in such cases a slight laceration may cause a great amount of trouble. Simple laceration of the cervix, unless it destroys the sphincteric power of the uterus, does but very little harm, provided there is no disease of the glands or follicles and no sepsis following labor. He believed that Dr. Mitchell had operated in cases which could have been cured, probably, by treating the conditions which were complicated by the laceration of the cervix.

LACERATED CERVIX SHOULD NOT BE SEWED UP

until it gives rise to symptoms, and when it does produce symptoms there is some disease behind it that needs treatment.

Dr. Mundé would never operate on what had been called the stellate laceration, unless there were special symptoms referable to what had been known as the cicatricial plug, and he might not even then. The bifid laceration might require an operation, providing it gives rise to symptoms. He never considers a laceration with regard to operation unless it produces symptoms; its mere existence does not call for sewing it up, no matter how large it may be, or how much everted.

When the cicatricial tissue makes pressure deep into the cellular tissue, and is attended by pain and reflex symptoms, the operation is justifiable. When the eversion is large, the menopause is not far off, and there is free discharge, he would operate, because of the liability to the development of epithelioma. He did not agree with Dr. Chadwick, of Boston, who had recently published that there was no danger of epithelioma developing from lacerated cervix, simply because he had had cases that proved to the contrary, and had no doubt that

THE LACERATED CERVIX IS MORE LIABLE TO BECOME THE SEAT OF MALIGNANT DISEASE,

if the eversion and erosion, etc., are sufficient, than is the cervix that is not in a torn condition.

He regarded it as a mistake when the circular artery was cut. He thought that in about ten per cent. of the cases the operation failed. He also regarded five or six sutures to the inch as more than was necessary. He utterly condemned placing the external os anywhere except where it belonged, and where it could receive insemination.

Dr. A. F. Currier agreed with the conservative remarks of the last two speakers, and had found that he declined more and more to perform the operation. He regarded five or six sutures to the inch as too many, and very liable to interfere with proper circulation.

Dr. Mitchell, in closing the discussion, said that only a few applications of nitrate of silver were required, hence its deleterious effects need not be produced. Where the case demanded an operation, it should be performed without much delay. He thought it was understood by all that the operation should not be performed unless called for by symptoms. He had not been able to give much relief without, in most cases, an operation to restore the contour of the cervix; but by cutting away these follicles and granulating tissue, reaching healthy tissue, and then closing the wound with silver-wire sutures, he had cured his patients.

He was unable to see how Dr. Mundé could cure a case of stellate laceration of the cervix without first cutting away all the torn tissue completely, and converting it into a straight, large, open wound.

TUBAL PREGNANCY.

Dr. Wylie opened the discussion on this subject by briefly narrating three cases. The points which he made were, that it was difficult to make a positive diagnosis; that if made, electricity should be used, but that if it failed he would operate at once; that if he had the placenta to deal with he would, if he could feel sure that he could do so perfectly, tie off the blood supply, and then remove it.

Dr. A. F. Currier, on behalf of Dr. J. E. Janvrin, read the history of a case and exhibited the specimen. Dr. Janvrin would perform laparotomy whenever the first symptoms of internal hemorrhage occurred. The primary rupture—which occurs in the superficial artery without rupture of the sac—which is sure to be repeated, is the cause of the colicky pain-collapse and other grave symptoms, and indicates

THE PROMPT PERFORMANCE OF LAPAROTOMY.

Even before symptoms of rupture develop, he would urge the performance of laparotomy.

Dr. J. West Roosevelt presented a specimen without history other than than it was removed from the body of a woman who died, in Roosevelt Hospital, of syphilitic tumor of the brain. The fœtus was between six and seven months old, and had changed into a condition resembling

ADIPOCERE.

The tumor had been carried for many years, and had not given rise to symptoms.

Dr. P. F. Mundé gave a brief history of three cases of tubal pregnancy; of extra uterine fœtation he had seen six cases. He believes that a positive diagnosis can be made, notwithstanding the stricture placed by

MR. LAWSON TAIT ON DR. COE'S PAPER,

in which he said that it could not be done, and then modified it by saying that he wished to say that he had never seen such a case. He regarded

TYMPANITES AS A GRAVE COMPLICATION

He would not operate at once, but would wait a little in primary rupture, and be governed by the general condition of the patient. He regretted that he did not perform laparotomy in one case.

Dr. J. Lewis Smith exhibited a specimen removed from the body of a woman, whom he saw with Dr. Griswold, and who was suddenly attacked with severe pain in the lower part of the abdomen, but without vomiting, and did not go into

COLLAPSE UNTIL ABOUT SIX HOURS AFTERWARD.

She died sixteen hours after the occurrence of the rupture. Her catamenia had continued throughout her pregnancy.

Dr. Brown, of the Carnegie Laboratory, who made the autopsy and had examined the specimen, reported that there was a large quantity of blood in the peritoneal cavity, but there was *no evidence of peritonitis*. The interesting features of the specimen were the presence of a decidua, the extreme thickening of the walls of the uterus, and the extreme thinness of the walls of the sac at the site of the rupture. As to

THE PRESENCE OF THE CATAMENIA,

Dr. Wylie said that this was a symptom that could not be depended upon, and The Chairman remarked that irregular discharges of blood were commonly present, but it was believed generally that true catamenia were absent.

Dr. R. A. Murray then presented a specimen of

RUPTURE OF THE UTERUS.

It was interesting from the fact that an absolute diagnosis was not made. The woman was twenty years of age, single, and a primipara. There was nothing special concerning her labor except the *absence of all the usual symptoms of rupture*. There were no violent labor pains at any time.

FORCEPS WERE USED,

because the fœtal heart could not be heard. After labor there were no symptoms pointing toward rupture. There was some pain in the abdomen, which became tympanitic, but the lochia were of a bright-red color and absolutely free from odor. However,

THE FACIES OF THE PATIENT INDICATED GREAT DEPRESSION,

and an examination was made, under ether, when it was found that rupture had occurred upon the right side at

the vaginal junction and had extended into the body of the uterus.

There was a fair amount of milk secreted. Up to the seventh day there was the history of moderate septicæmia, the highest temperature being 102° F. Death occurred several days afterward, and at the autopsy there were found

GANGRENOUS ENDOMETRITIS,

with swollen and œdematous tissues and diphtheritic exudation upon both uterine and vaginal surfaces.

Tympanites and a contracted pelvis prevented a proper examination until the fourth day after labor, when he was able to let out a large quantity of very fetid blood.

SEPTICÆMIA DEVELOPED NOTWITHSTANDING THE BICHLORIDE INJECTIONS,

and the fetor was controlled, but the patient died, as he believed, in consequence of the initial poisoning. He also believed that laparotomy would have given the patient a better chance for recovery.

Dr. Wylie said that in cases where the septic trouble was confined to the broad ligament, he would dilate freely, put in a drainage-tube, and wash out the cavity thoroughly.

Dr. Mundé would extract the child through the rent in the uterus from the abdominal cavity, if he could do so readily; if not easily done, or the placenta had escaped into the abdominal cavity, he would perform laparotomy for that purpose. If, however,

THE PERITONEUM OF THE UTERUS

was not ruptured, laparotomy should be left out of the question.

The Section then adjourned.

Correspondence.

NITRO-GLYCERINE IN THE TREATMENT OF EPILEPSY.

To the Editor of The Medical Record.

Sir: In the interesting discussion on the pathology and treatment of epilepsy, at the meeting of the New York Academy of Medicine, on March 3d, a report of which is published in your issue of the 19th, I was surprised to see no mention made of nitro-glycerine as a medical agent in this intractable affection.

My own experience with it is limited to a few cases, but the reports as to its value have been quite numerous, and are of such a character as to render further trials of it advisable.

In one of my own cases the result was most gratifying. A girl, fifteen years of age, of bad family history—her mother and grandmother having died insane—had been a sufferer from epilepsy for two years. Her general health was good and her menstrual functions properly performed.

I saw her first in consultation with Dr. Newman, of Orange County, Va., on November 1, 1885; she was then having convulsions almost every day, and sometimes twice in twenty-four hours. The bromides had been faithfully tried with but partial relief. She was at once placed upon nitro-glycerine, one drop of a one per cent. solution being given her three times a day. She had a convulsion on November 9, 1885, and did not have another until about November 1, 1886—the nitro-glycerine having been continued without intermission during the whole of this time. On November 13, 1886, I saw this young lady again; she had then had two slight convulsive seizures and had on several occasions been "dazed," as she expressed it. The dose of nitro-glycerine was increased to one drop and a half three times a day, and she has had no return of either the convulsions or the "dazed feelings" since.

In view of the fact that the *hygienic* management was precisely the same before and during the administration of the nitro-glycerine, it seems fair to attribute the benefit in this case to its use.

In another case the convulsive seizures were kept under control for some weeks; but it was impossible to induce the parents of the patient in this case to persist in the use of the remedy, they having been taught that epilepsy was incurable. In several other cases which have fallen under my observation there has been improvement, but there has not yet been a sufficient interval of time since the treatment was commenced to say what the ultimate result will be.

As is well known, nitro-glycerine produces a disagreeable flushing of the face when it is first taken, but this effect is very transient, and the slight headache which sometimes accompanies it is equally so.

William C. Dabney, M.D.

University of Virginia.

New Instruments.

SOME NEW NASAL, PHARYNGEAL, AND LARYNGEAL INSTRUMENTS.[1]

By S. Sherwell, M.D.,

Brooklyn, N. Y.

In connection with my dermatological work I have to do with a not inconsiderable number of diseases of the upper air-passages, often certainly as syphilitic annexes, but far more frequently of the character of non-specific affections. At one clinic, that for skin and throat diseases at the Brooklyn Eye and Ear Hospital, I see about five hundred new throat and nose cases each year, which, together with private practice of the same kind, and duties in other hospitals, would bring the total amount to very considerably over one thousand fresh cases annually.

I have consequently had to meet, and get over as best I might, most of the difficulties that occur in these regions in the way of operative interferences; and although I have a fair array of instrumental armamenta for that special work, still I suppose no man has at his command all the special instruments made for help in such cases; and, in fact, sometimes, if not frequently, he is called upon to either modify some existing instrument, or to devise new ones (as I claim to have done in the instruments I now lay before you) to meet the exigencies of the existing situation or to supply deficiencies. The instruments in question, I hope, in many cases will serve to fill the traditional "long felt want," and I shall publish them as Sherwell's Nasal, Pharyngeal, and Laryngeal Scissors.

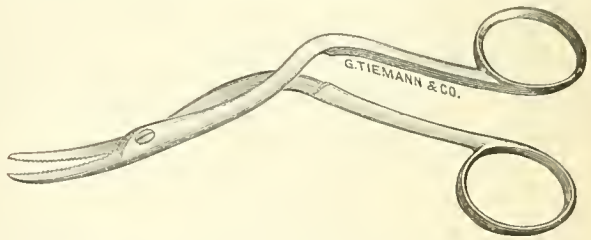


Fig. 1.—Nasal Scissors.

The nasal scissors are intended for removal of neoplastic growths, or hypertrophic tissue, from the anterior, or middle, or even the deeper portions of the nares, and consist of a pair of serrated blades similar to the alligator-tooth scissors, slightly concavo-convex, and with handles bent downward in the long axis so as not to obstruct the vision while operating.

The pair shown were made about five months ago, for operation on the nose, for the removal of hypertrophied turbinated tissue in the person of a well-known professor

[1] Read before the State Medical Society at its Annual Meeting on February 3, 1887.

of surgery, and succeeded in their purpose fairly well. It will be noticed that they are best adapted for the left nares—on that side the trouble was present in this case; but they can be, and have been, used for right nares by inverted handling. The notched teeth prevent slipping and pushing of the tissues away, as can be best demonstrated by cutting a piece of india-rubber with them, and then doing so with the ordinary smooth-scissor blades. It will be noticed, also, that the shanks of the handles are narrowest when the blades are open nearly, if not fully, to the greatest necessary extent.

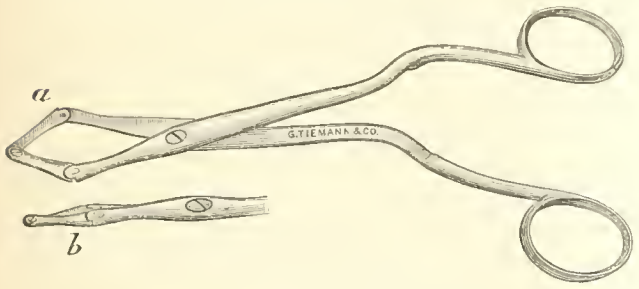

FIG. 2.—Pharyngeal Scissors.

Figs. 2 and 3, pharyngeal and nasal, I give in order of priority of make.

In Fig. 2 I have tried to construct an instrument capable of being used by anyone, however inexpert; that should run no risk of piercing the pharynx, or the important vessels back of the tonsils, etc., no matter what unguarded movements a nervous or intractable patient might make during the operation. This is intended to trim a pharynx, to cut out small, teat-like projections of a fretted or ragged tonsil, which are so often seen; and which are, from their size and shape, impossible to remove by the tonsillotome; and also as a most useful uvulatome. The advantage, so readily seen by the expert, of its needing no help with forceps, thus leaving one hand free for tongue-depression or for steadying the head of the patient, seems to me obvious enough; and it has certainly so proven in the relatively few cases in which, owing to its recent make, I have had an opportunity to use it.

The instrument, as will be noticed, is an absolutely pointless scissors, hinged about one-third of the distance from the extreme end, and thus composed, as will be seen, of four blades, but forming but two, as it were, by cutting at the hinge-joint as well, when the handles are closed. This is difficult to make satisfactorily, but the Messrs. Tiemann have surmounted this difficulty, and doubtless it will be even improved upon by their skilled workmen in the future.

The instrument when open, and it should be ordinarily introduced that way if the pharyngeal space is shallow, has an inside cutting surface something like the old Roman spear-head, the apex directed toward the operator; it needs but one word to explain why that is made so: This serves to thrust the enclosed tissues forward to the operator instead of away from him, as is the case with the ordinary curved or straight scissors.

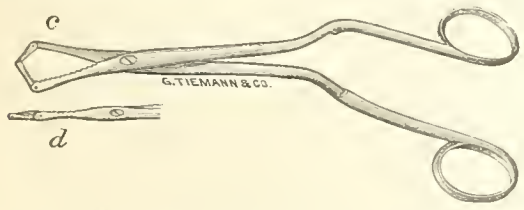

FIG. 3.—Nasal Scissors. *c*, Blades open; *d*, blades closed.[1]

I think this idea has the merit of novelty at least, for I cannot recall any other instrument in which the cutting is going on all round at the same moment save in écraseurs.

[1] By draughtsman's error the proximal blades are not made long enough; angle of distal blades correct; the lumen should be considerably longer.

I have purposely given Fig. 3 out of its natural sequence, although it is intended for the same use as Instrument No. 1, *i.e.*, for the removal of hypertrophic and other tissues from any part of the anterior or deeper nares; I think it has many advantages over the first shown, but is more complex. It is, as will be seen, but a modification of the pharyngeal scissors just described, but is more delicate and has serrated edges. It will be noticed that the inside cutting edge is not that of the Roman spear, but rather that of an Indian arrow-head or javelin; this is accomplished, as is evident, by making the site of the hinged joint nearer the extremity of the blade. I operated with it on January 29, 1887, the day it came from the makers' hands, having reserved a patient with the growths above named; it worked very well. It needs no special instruction in its use, is absolutely free from danger, and causes, it may be said, no hemorrhage.

I think the instrument made a little stronger might be better.

The last instrument (Fig. 4), though it has, and must have, more limited use and a far narrower circle of users, I am somewhat enthusiastic over. Probably all laryngologists have been bothered (we may take the confessions of the most noted at least, that they have been) to get hold of and crush or cut, or both combined, those little or big neoplasms that occur, fortunately, relatively so rarely in the recesses of the larynx. I average three or four laryngeal tumors, I think, annually, and have a fair supply of Stoerk's, Mackenzie's, Schrötter's, Fauvel's, etc., instruments, but every now and then I have been exceedingly annoyed at the elusiveness of these little tumors situated on the vocal cords and elsewhere in that vicinity. I have sometimes tried all my own tools and borrowed others, and worked till my patience or that of the patient was exhausted; this is apt more particularly to be the case in and of those sessile outgrowths, papillomata, or what not, from one or the other vocal cord.

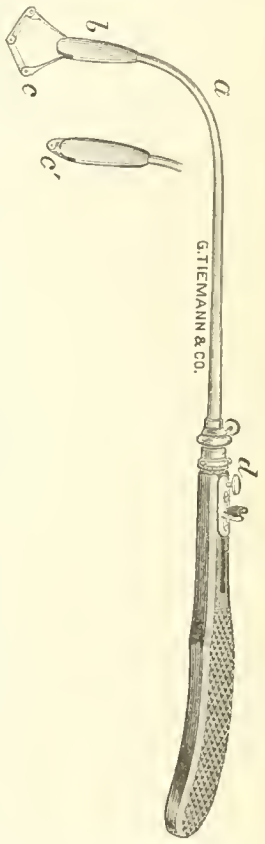

FIG. 4.—Laryngeal Scissors. *a*, Tube: *b*, sheath, cutting edge below slot; *c*, instrument retracted into sheath; *d*, sliding retractor-grip on wire.

The instrument now shown is then adapted to one of Schrötter's tubes and handles, and consists virtually of the same idea as that of the hinged and jointed four bladed scissors just as given in the preceding two, naturally very much lessened in size and with yet a differing lumen. The instrument is introduced closed into the larynx, allowed to expand by the automatic spring arrangement on pressing the wire attached to the finger-piece, and when, as the expert will know, it is at or about the site of the growth, is redrawn up into the tube, and into the slot in the tube, by retracting finger-pressure.

The instrument may not cut the growth off cleanly, but a very slight pushing and retracting will divide the tissues met with there. The cleanness of separation is of little consequence anyhow, for we know, as a matter of fact, that the nutrition of these small neoplasms once essentially interfered with by crushing or cutting, they tend to disappear, as do warts and such, by astringent and alterative applications being applied with the brush, etc.

I believe this instrument to be a good addition to the existing armamenta for laryngeal operation, and hope it

and the others will commend themselves to the gentlemen more especially interested in such work.

Owing to its recent make I have had but one opportunity of using this instrument on a laryngeal growth; it succeeded then admirably. One point omitted in description of instrument is, that there is a screw-joint at junction of shaft and tube, permitting any degree of rotation of cutting surfaces.

I also believe that the principle of this hinged and pointless scissors would adapt itself well for use in some of the other mucous openings and cavities of the body. The four blades closing at once give it an essentially écraseur like action, so that hemorrhage is usually extremely slight.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 3 to April 9, 1887.

HOFF, JOHN VAN R., Captain and Assistant Surgeon. Ordered for duty at Fort Reno, Ind. Ter. S. O. 43, Department of Missouri, April 4, 1887.

CORBUSIER, W. H., Captain and Assistant Surgeon. Granted leave of absence for one month. S. O. 35, Department of Arizona, March 29, 1887.

BURTON, H. G., Captain and Assistant Surgeon. Ordered to Plattsburg Barracks, N. Y., for temporary duty. S. O. 78, A. G. O., April 5, 1887.

LA GARDE, L. A., Captain and Assistant Surgeon. Ordered for duty at Fort Assiniboin, Mon. Ter. S. O. 78, A. G. O., April 5, 1887.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 9, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	15	5
Scarlet fever	58	6
Cerebro-spinal meningitis	2	1
Measles	79	10
Diphtheria	82	33
Small-pox	6	4
Yellow fever	0	0

A DISPENSARY WHICH TRIES TO CORRECT THE ABUSES OF MEDICAL CHARITY.—In the recently published Seventeenth Annual Report of the Manhattan Eye and Ear Hospital, which now occupies the beautiful new building erected for it on Park Avenue, near the Grand Central Depôt, are to be found some facts of special interest. From it we learn that constant and vigilant efforts are to be made to exclude from the benefits of the hospital all who are not, by reason of poverty, deserving of gratuitous care. A registrar occupies a desk near the door, and asks the following, among other searching questions, of every applicant for treatment: "How much money have you in savings or other bank?" "How many persons are dependent on you for support?" "How much rent do you pay?" "Can you afford to pay anything for medical advice?" During the year just past two hundred and fifty-nine applicants were rejected after such inquiries, having acknowledged that they were able to pay. Moreover, after such inquiries have been made and satisfactorily answered, the beneficiaries or their friends are asked to contribute what they can to the treasury of the hospital; and it is of interest to learn that during the past year there was contributed by the acknowledged poor beneficiaries the sum of $6,614. All the money thus received was expended for the benefit of the hospital and dispensary patients.—Cor. *Am. Jour. S. and A.*

PROFESSOR SAINT GERMAIN, of Paris, for phimosis uses a pair of pointed forceps which he introduces as far as the meatus, and then spreads it until he can pass the gland through the opening. The operation is followed by less irritation than circumcision, and the results seem to be good. He is not a friend of the Jewish idea of the superfluity of the foreskin; in fact, he says that when you cut it away you have in a manner deformed the patient and deprived him of a tissue which he believes to contribute to the perfect healthiness of this most important gland.

DR. MARTIN, OF BERLIN, operates with a rapidity that is wonderful. I have seen him remove an ovarian cyst and close the wound in seven minutes, and have frequently seen him do the operation inside of ten minutes. He considers despatch a prime element of success, and thinks that Lawson Tait's idea of a small abdominal incision is an erroneous one. He thinks that too many assistants are bad, and tells of performing an ovariotomy entirely unassisted, those he depended upon being taken with a fainting fit and hence unable to perform their duty. —Cor. *Chicago Medical Journal.*

PROFESSOR BERGMANN is the most painstaking man I have seen operate, and his results are the best; that is, his wounds heal more uniformly without suppuration or constitutional reaction. He condemns the use of instruments with horn handles, believing that it is difficult to render them aseptic. I had the good fortune to attend his clinic during the college vacation, when he was lecturing to and operating for the instruction of the army surgeons. There is a feature about his operations that, in my opinion, plays a most important rôle, and that is the care with which he ligates every bleeding vessel, however small. For this purpose he uses only catgut, even to ligate the femoral artery.—Cor. *Chicago Medical Journal.*

A STATISTICAL VIEW OF THE TOXIC POWER OF IMPURE (AMYLIC) ALCOHOL.—To poison an animal with pure ethylic alcohol it requires as many times seven grammes seventy-five centigrammes as there are kilogrammes in its weight; whereas with pure amylic alcohol it would not take more than one gramme ten centigrammes per kilogramme. In other words, supposing a man weighing eighty kilogrammes, it would require six hundred and twenty grammes of ethylic alcohol to kill him, while with amylic alcohol it would take only eighty-eight grammes. These figures prove that people now become alcoholic with seven times less liquor than formerly.

PROFESSOR LANNELOGUE, in his lectures at the School of Medicine, treated, for the first part of the session, of injuries and diseases of the head, spine, and neck. For injuries of the skull he still adheres mainly to the use of the trephine, claiming that when the operation is performed antiseptically it gives good results. On the other hand, Bergmann has abandoned this instrument, and in a late number of *Volkmann's Vorträge* he takes occasion to discuss this subject in a most thorough manner, showing that by substituting the hammer and chisel immensely better results are obtained. In speaking of Pott's disease of the spine Professor Lannelogue says that the microscope has settled the question as to its tuberculous origin. As to the plaster-of-Paris jacket of Sayre, he says that the idea of keeping the two diseased surfaces separated by this appliance is irrational and impracticable. He puts his patient in a horizontal position and keeps him there for months together, taking him in the open air as much as possible to preserve the general health.—Cor. *Chicago Medical Journal.*

Original Articles.

ON THE PROPER SELECTION OF CHLOROFORM OR ETHER AS AN ANÆSTHETIC.

BY ARPAD G. GERSTER, M.D.,

NEW YORK.

THE question of safety in anæsthesia is of great interest to the general medical public, but of an absorbing interest and of paramount importance to the hospital surgeon, whose duty calls him to make daily use of anæsthetics in operations.

Insensibility has to be induced under the most varying individual conditions of age, health, or disease, for the alleviation or cure of disorders of various regions; and truly it can be said of the hospital surgeon that the observation and study of the normal and abnormal phenomena of anæsthesia, with their advantages and constant danger, are an ever-present accompaniment of his avocation.

Before entering upon the discussion of the merits of the question that is to occupy us, a few words may be appropriate regarding the spirit which unfortunately has characterized many of the deliberations instituted for the sake of elucidating the principles which should govern the physician's choice of anæsthetics.

Instead of the maintenance of the unbiassed and calm tenor of the scientific observer's mind, so indispensable to the arrival at reliable and trustworthy conclusions, we have seen, too often, the zealot's vehemence, the partisan's lack of candor, and the exaggerations of a political controversy enter into the debates had on the merits of the different anæsthetics.

I wish to enter a solemn protest against this unscientific way of conducting an inquiry for the discovery of truth, and this mainly because I am convinced that the truth which we strive to discover cannot be arrived at unless we cast off all prejudice and passion and approach our problem with the spirit of candid inquiry. Pains have been taken to exclude material not gathered within the personal experience of the author, all conclusions arrived at and views taken being based upon personal observation made during an arduous hospital service of eight years.

First of all, let us clearly state that both chloroform and ether are dangerous anæsthetics, as a long array of fatal accidents recorded in medical literature has abundantly shown. The relative amount of danger caused by chloroform or ether anæsthesia is best characterized by the fact elicited in the series of sphygmographic observations made by Kappeler, that chloroform invariably produces a very marked depression of the vaso-motor function, and that this depression occurs only occasionally in ether anæsthesia.

The practical significance of this fact is, that chloroform is the infinitely more powerful agent, and that its administration requires a greater amount of care, caution, and circumspection. But this fact is by no means a sufficient ground for its unqualified condemnation. It is true that the administration of chloroform involves a greater responsibility as long as the patient is kept under its immediate influence; but consciousness being restored, the dangers of chloroform anæsthesia are past, as no secondary deleterious consequences are recorded that could be charged to the use of chloroform.

Ether, on the other hand, has not caused as often immediate death on the operating-table as chloroform; or, put in another way, recklessness in its administration has not been followed as inexorably by disaster as in the use of chloroform; but the dangers of ether anæsthesia are by no means overcome from the moment that the patient has recovered consciousness. Numerous deaths from acute nephritis and catarrhal pneumonia, chargeable to ether anæsthesia, abundantly attest this.

To sum up the proposition, it may be said that, whereas chloroform is undeniably the more powerful anæsthetic, the immediate danger of its administration is greater, but is past as soon as anæsthesia has terminated, no secondary effects following its exhibition.

Ether being the less powerful anæsthetic, its immediate danger during narcosis is less, but is in a great measure compensated by secondary dangerous affections of the lungs and kidneys, occasionally produced by its administration.

The statement made by zealous advocates of ether, that its administration is always, and under all circumstances, safer than that of chloroform, does not coincide with truth, as we shall presently see.

The main object of this paper is to point out, on the one hand, the conditions under which chloroform is the more dangerous anæsthetic and should never be used; and, on the other hand, to show when ether is the more dangerous narcotic, and therefore should not be employed. Both agents are a very valuable part of our pharmacological equipment, and their intelligent employment should be fully understood by every well-educated physician. Such one-sidedness as prevails in some of our Eastern medical centres, where physicians are frequently met with who fear and shun the use of chloroform even where it is clearly indicated; where physicians exist who confessedly do not know how to administer chloroform, *because they never have seen it done;* where the otherwise excellent schools clearly neglect to impart to their scholars by practice the knowledge of administering chloroform—such one-sidedness cannot stand serious criticism, and must lead to the comparatively frequent detriment of those who intrust us with their welfare during an illness requiring anæsthesia.

The false cry that ether anæsthesia is entirely free from danger has led to another grave condition of things observed among the young men who seek and gain hospital positions. Nowhere else did the reader of this paper see an amount of recklessness exhibited in the administration of anæsthetics equal to that in the cities where chloroform is tabooed; especially in cases that take ether badly, and in whom relaxation is not easily accomplished, matters are forced in a way that must excite the gravest apprehensions for the safety of the patient. Usually these are the cases of those addicted to the immoderate consumption of alcohol, persons of enfeebled circulation and impaired respiratory organs.

More and more ether is poured on, until the cyanosed patient relaxes, his stertorous breathing indicating that an ever-increasing mass of viscid mucus and saliva is flooding his trachea and bronchi. The sensitiveness of the larynx and trachea is abolished, and if vomiting occurs, especially where the inexperienced anæsthetizer neglects to conduct the vomited matter out of the mouth, gastric contents find their way into the bronchi, and a catarrhal or even septic pneumonia follows, resulting in death, which, however, is never charged to the account of ether.

It being admitted that, on the whole, ether is the less dangerous anæsthetic, preference should be given to it, especially when anæsthesia has to be conducted by an inexperienced person. Ormsby's inhaler is better than Allis' or its modifications, as less ether is required by its use to induce and maintain full anæsthesia, and recovery is more prompt on this account.

Ether is counter-indicated in all affections impairing the integrity of renal function.—To Emmet belongs the honor of having first pointed out the danger of administering ether in chronic or acute renal disease. An increasing number of recent observations fully corroborates his view taken in this matter. As an illustration the following case may be quoted here :

Case I.—I. M——, aged seventy-three, admitted August 21, 1883, to Mount Sinai Hospital, on account of incarcerated right inguinal hernia of three days' duration. Constant feculent vomiting; good pulse, sixty beats per minute were present. Late at night herniotomy was performed under ether, after an unsuccessful attempt at taxis. The sac being exposed, a knuckle of gut containing an oblong, square body could be felt. This body gave way to moderate pressure of the fingers, after which the gut could easily be replaced into the abdominal cavity without opening the sac. The patient's daughter reported on inquiry that her father had had a large meal of potato-soup before he was taken sick. It was concluded that a square piece of potato, bolted by the toothless old man, had been the cause of the strangulation. The operation had lasted twenty-five minutes. The patient recovered promptly from the anæsthesia, and exhibited no symptoms indicating a disturbance of the wound. August 23d, marked somnolency was noted, with very scanty secretion of urine, which was found to contain much albumen and hyaline casts. The wound was healed August 29th, nothwithstanding the fact that uræmia, with stupor and much vomiting, continued to exist, to which the patient succumbed in a comatose state, September 1st.

There had been no indication of kidney trouble previous to the operation.

Those who wish more convincing proof on this subject are referred to the publications of Emmet, Van Santvoord, Wesley M. Carpenter, Dr. Millard, William F. Norris, and Dr. Turnbull.

That chloroform is a much safer anæsthetic in Bright's disease and allied morbid conditions of the kidneys than ether is abundantly attested by the fact that it has been employed for hours together, without any accident, in uræmic eclampsia of gravidity. A careful examination of the urine should invariably precede every anæsthesia, and the presence of albumen or casts should be considered a positive counter-indication to the use of ether, and a direct indication for the use of chloroform.

Serious objection to the use of ether as an anæsthetic must be raised in another numerous class of cases. *Chronic catarrhal affections of the bronchi of the aged, and, perhaps, of infants, frequently develop into catarrhal pneumonia terminating in death of the usually enfeebled patients in question.* Very little has been said or written on this subject heretofore, and the reader of this paper deems it his duty to draw the attention of the profession to his experience regarding this matter.

The very profuse secretion and inspiration of saliva into the air-passages seems to be the main cause of the pneumonia observed after the inhalation of ether. The cold fumes of the drug seem to blunt the sensibility of the bronchial mucous membrane to such an extent that the entrance and presence of even vomited matter does not excite a sufficient stimulus to vigorous reflex action or coughing, especially at the end of prolonged anæsthesia. Hence, what German authors call "Schluckpneumonie" is comparatively frequent after the use of ether, and frequently terminates fatally in those previously afflicted with chronic lung trouble.

Case I.—M. B——, aged forty-three, admitted to Mount Sinai Hospital, August 20, 1883, with a very tight cancerous stricture of the rectum, complicated with periproctitic abscess. On account of this affection and a chronic bronchitis of a mild type her general condition was rather poor, but not sufficiently so to prevent her from attending to her household duties. Lumbar colotomy was performed, under ether, August 22, 1883, the patient being placed on the operating-table on her right side. August 23d, in the morning, a severe chill and high fever set in, the thermometer indicating 105° F. in the axilla. The wound was examined, but was found pale and normal. The next day, August 24th, pneumonia of the entire right lung was diagnosticated, to which the patient succumbed, August 26th. Post-mortem examination revealed dense infiltration of the entire right lung. The colotomy wound was found healed throughout by adhesion.

Case II.—M. H——, aged sixty, admitted to Mount Sinai Hospital, for castration of a tuberculous testicle, on January 23, 1887. Operation was performed January 24th, under ether. January 26th, at 2 P.M., a severe chill set in, followed by an elevation of the temperature, which reached 106° F. in the rectum at 6 P.M. Dulness on percussion, corresponding to the lower posterior portion of the right lung, was made out. The wound was examined at the same time, and was found in a thoroughly correct condition. The pulse was fluttering and very frequent, respirations were shallow and hurried, the patient comatose. He died the same evening at 9.55. Post-mortem examination, done the following day, showed lobar pneumonia of the lower part of the light lung in the stage of bloody engorgement. Wound throughout adherent; peritoneum normal.

Case III.—S. Y——, aged sixty-one, admitted November 12, 1886, to Mount Sinai Hospital, with far-gone cancer of the rectum, for which inguinal colotomy was performed, November 15th, under ether. November 16th the temperature rose to 103.2° F. November 17th, catarrhal pneumonia of the lower part of the left lung was made out, which gradually traversed the entire left lung, causing a number of febrile exacerbations and a very rapid and alarming deterioration of the general condition. The patient's sufferings were very much aggravated by the involvement of the prostate and neck of the bladder by the cancerous growth, causing frequent and painful micturition, and ultimately cystitis and pyelonephritis, to which the patient succumbed, December 23d. Profuse bronchial secretion of purulent character was observed up to the termination of the case. The inguinal colotomy wound healed by primary adhesion as far as the peritoneal sutures were concerned. The muco-cutaneous suture parted in a considerable portion of its extent on account of sloughing of a circumscribed part of the skin, which was, however, readily detached and gave way to a firm cicatrix.

The house-surgeon of the German Hospital kindly extracted notes of three cases of pneumonia, following the administration of ether, observed during the year 1886 in that institution.

In Case I., a patient twenty-five years of age, fatal pneumonia set in the day following an extirpation of the inguinal glands. Before the operation dulness over the apex of the right lung, due to past pleuro-pneumonia, was noted. The affection reappeared on the same side.

In Case II. perineorrhaphy was performed, under ether, on a woman fifty years of age. Immediately after the operation pneumonia set in, to which the patient succumbed. Post-mortem examination revealed a fatty heart, pulmonary emphysema, and chronic bronchitis in addition to chronic nephritis.

In Case III., a boy, sixteen years of age, severe pneumonia followed an extirpation of inguinal glands under ether. Patient recovered.

Five cases of serious bronchitis were also observed, in 1886, in the same institution, after the use of ether.

Four more cases of pneumonia, following directly after the use of ether as an anæsthetic, are recorded in my notes; but as the operations done in these cases were performed on the trachea, tongue, and lower jaw, and the entrance of blood may have possibly complicated the causation, they will not be urged as a part of the argument.

There is no doubt that as soon as the attention of the profession is duly called to the frequency of pneumonia following the administration of ether as an anæsthetic, more cases of this kind will be forthcoming.

Narcosis by ether in small children suffering from affections of the air-passages was never employed by the reader so far, preference being given to chloroform. On the whole, it may be stated, however, that infants whose lungs were sound were frequently anæsthetized with ether without any unfavorable consequences. They have invariably taken the anæsthetic easily and well, and have recovered promptly from it.

In a third rather numerous class of cases ether anæsthesia has been found impracticable, because unconsciousness could not be induced; or because tolerance was attained, but violent retching, coughing, or general *tonic and clonic convulsive movements of the patient rendered the performance of an operation either totally impossible or very hazardous.*

In some operations, as, for instance, incising a fluctuating abscess, or scraping an old sinus, rigidity or imperfect loss of sensation on the part of the patient may be annoying, but is no absolute bar to the proper performance of the contemplated step. But in herniotomy—in fact, in all operations involving the peritoneum—in the removal of deep-seated tumors from the vicinity of large vessels, in operations usually done in the lithotomy position, as for hemorrhoids and stone in the bladder, not only loss of sensation but absolute relaxation of all voluntary muscles is an indispensable condition to success. It has been positively stated in text-books, and also *viva voce*, that the failure to induce full anæsthesia by ether in six or eight minutes must be charged to either poor ether or to incompetency of the person administering the vapor.

This statement is contrary to the facts, as the experience of the reader and that of every hospital surgeon doing much work with the aid of anæsthesia can abundantly attest.

In spite of careful preparation of the patient, and proper administration of ether by a competent and experienced physician, relaxation could not be produced positively in 11 out of 125 cases observed in the German Hospital during the year 1886. Sensation was either not abolished or where tolerance was reached general rigidity or clonic spasms were so pronounced that operating with any degree of comfort or safety was out of the question. A change of the anæsthetic was generally followed by the desired state of tolerance and relaxation.

For the sake of illustration some of these cases may be quoted:

Case I.—H. M——, sixty-two years of age, February 23, 1886; radical operation, according to Czerny's method, for a very large and irreducible inguinal hernia, at German Hospital, under ether. Spasmodic coughing with cyanosis persisted to such an extent, in spite of a hypodermatic injection of morphia, that the operation had to be suspended. At each paroxysm of coughing the intestines rushed out of the unusually wide abdominal ring with such a force that operating was absolutely impossible. There was a wide adhesion of the prolapsed thick gut to the neck of the hernial sac and complete reposition was impossible until the adhering portion of the gut was dissected up, a delicate part of the operation at best, and entirely unsafe, and even impossible, while the coughing and retching lasted. After renewed unsuccessful attempts with ether, lasting for over ten minutes, this plan was given up in favor of chloroform, which promptly produced the desired condition, under which the operation could be satisfactorily proceeded with and finished.

Case II.—S. K——, aged twenty-six, incision of relapsing perityphlitic stercoral abscess, March 9, 1886, at German Hospital. Ether being administered with Ormsby's apparatus for twenty minutes, neither tolerance nor relaxation was induced; change to chloroform at once produced the desired state, and the operation was done without interruption.

Case III.—J. M——, aged thirty-nine, December 18, 1886, laryngo-fissure, at Mount Sinai Hospital, for the removal of endolaryngeal tumors. Ether was administered and at once produced such alarming spasms of the glottis, with cyanosis and imminent suffocation, that it had to be discontinued; chloroform being given, pleasant and undisturbed anæsthesia was at once produced, and the tumors were removed without serious difficulty.

Case IV.—Mrs. C. K——, aged thirty, scraping and removal of tuberculous lymphatic glands of neck, done at the residence of the patient, February 27, 1887. Ether was freely given by Ormsby's apparatus for a considerable time, but failed to produce either complete loss of consciousness or sensation. The small operation had to be done as well as could be, and under much difficulty, on account of the exaltation and struggling of the patient, lasting for a disproportionate period of time. Chloroform was refrained from, as it had produced dangerous collapse on a former occasion. Local anæsthesia by cocaine would have very likely been the best expedient in this case.

Having reviewed the subject in question, the result arrived at may be summed up in the following propositions:

1. *Ether as an anæsthetic should not be used* in cases of present or even suspected acute or chronic nephritis.

2. On patients suffering from chronic pulmonary affections, especially if they be elderly persons.

3. The change from ether to chloroform is justified and proper where complete relaxation and loss of sensation, indispensable to the performance of an operation, cannot be induced by the former agent, and where local anæsthesia by cocaine or the ether spray is impracticable.

Chloroform in the hands of a well-trained and conscientious anæsthetizer is just as safe as ether. Chloroform and ether may be properly put on a parallel with the extremely sharp razor on the one hand, and the school-boy's jack-knife on the other. Undeniably, infinitely more numerous and dangerous incised wounds would occur if every school-boy were permitted to carry a sharp razor, instead of his comparatively harmless pocket-knife. But physicians entering their profession should not stand on the level of school-boys.

Dr. John M. Farrington, who raised his voice with admirable courage in a recent number of the New York *Medical Journal* in favor of the more general use of chloroform as an anæsthetic, pertinently uses the following metaphor: "Now and then a man gets a piece of beef in his windpipe and dies from suffocation, yet people are not deterred thereby from the use of beef."

The undeniable fact of the greater handiness and more general applicability of chloroform should serve as a sufficient incentive to a more general cultivation of the use of this anæsthetic. Its safe use certainly presupposes a greater amount of vigilance and sound medical knowledge than seems to be required from the average etherizer. But no amount of zealotic vilification on the part of the etheromaniacs can dispose of the fact, that the highly trained profession of the continent of Europe, and of England, with the exception of a small fraction of the French, and a somewhat greater fraction of the English body medical, prefer to this day the use of chloroform.

There is only one *intrinsic* counter-indication to the use of chloroform—that is, a fatty and weak heart—where there are three to the use of ether. They are—fatty or weak heart, kidney and lung trouble.

The *extrinsic* counter-indication, namely, carelessness or incompetency of the anæsthetizer, is, no doubt, in-

finitely graver with chloroform than with ether. But for this there is help to be hoped for.

Insufficiency to induce full and satisfactory anæsthesia is quite frequent with ether; with chloroform it also occurs, though much more rarely.

Persons addicted to a regular, not necessarily an excessive, use of alcohol, very frequently "take ether badly." This phrase, so familiar to frequenters of operating-rooms, may mean several different things. It may mean that the patient does not lose consciousness or does not relax, and if ether is crowded, at once becomes asphyxiated and cyanotic, with irregular breathing and signs of imminent heart-failure. His pupils remain widely dilated throughout. The moment the ether cone is removed and breathing improves, his struggles and contractions are renewed. Thus such patients never attain a normal anæsthesia, but suddenly drop from a turbulent stage of excitement into an alarming condition of extreme narcotic intoxication.

Though the majority of these "bad etherizers" are users of alcohol, such a peculiarity is occasionally exhibited by absolutely temperate persons.

Case V.—L——, book-keeper, aged thirty-four, of teetotal propensities, was admitted to Mount Sinai Hospital as a private patient, to be operated on for external hemorrhoids. The patient was perfectly cool when anæsthesia by ether commenced. As soon as the effects of the anæsthetic became manifest, violent opisthotonos, with alarming spasm of the respiratory muscles and deep cyanosis developed, so as to compel interruption of the narcosis. On repeated attempts exactly the same state of affairs developed, even after a hypodermatic injection of eight minims of morphia solution had been given. Sensation was perfectly abolished, and but for the tetaniform spasm the operation might have been done. A change to chloroform did not improve things much, except that the cyanosis became less marked. Nothing remained to be done but to roll the patient over on his side, and to deligate the hemorrhoids under great obstacles. Much difficulty was experienced in gaining access to the anus between the rigid glutei muscles, and what with the convulsive shakings of the patient and the many stoppages caused by the turbulent narcosis, the performance was neither easy nor pleasant, but the end was finally accomplished. The patient was cured of his complaint. Had he been a very fleshy individual the operation would simply have been a matter of sheer impossibility.

Bright's disease, or pyonephrosis, is no counter-indication to the use of chloroform, as a considerable number of the reader's own experiences can attest, of which the following cases may serve as illustrations:

Case I.—S. O——, tailor, aged fifty-four, suffering from tight, impassable stricture of the membranous portion of the urethra, enlarged prostate, and fetid cystitis with pyelonephritis, was seen, March 23, 1886, by the reader, in consultation with Dr. Schwedler, the family attendant. In view of the fact that the stricture was very dense, the bladder extremely dilated, and the patient's peril very great, and after a number of unsuccessful attempts to enter the bladder *per vias naturales*, chloroform was administered on March 25th, and external urethrotomy was performed. Anæsthesia was very good and uninterrupted, and though the patient had lost a good deal of blood from a number of varicose veins surrounding the membranous part of the urethra, he rallied promptly from the anæsthetic, and made a very satisfactory recovery, as far as the irritability of the bladder was concerned.

In July, while using the waters of Richfield Springs, the patient's nephritic trouble became much aggravated, uræmia developing, to which he succumbed, August 10th.

Case II.—J. T——, wholesale liquor-dealer, aged sixty-two, had been suffering from milky patches of the tongue for fourteen years. Since the summer of 1886 two of the patches had turned into painful ulcers, one of them of the elevated kind, and having resisted all efforts at cure, finally a small particle of the growth was excised for microscopical examination. Epithelioma being diagnosticated, excision of one-half of the tongue was proposed. Examination of urine revealed hyaline casts and varying quantities of albumen. February 10, 1887, chloroform being administered, at Mount Sinai Hospital, the left lingual artery was exposed and cut through between a double catgut ligature. After this a platinum wire was carried, by the aid of Peaslee's needle, from the bottom of the wound through the base of the tongue, just forward of the epiglottis, into the oral cavity, and thence around the base of the tongue, close to the left anterior pillar of the fauces, from where another needle brought it back into the wound through the floor of the mouth. The galvanic current severed the left half of the base of the tongue from its attachments, and the thermo-cautery accomplished its division from the healthy remnant of the organ and from the muscles of the floor of the mouth. The loss of blood was very trifling, and the wound was packed with iodoform gauze. The anæsthesia was unusually good, and the patient made a feverless, prompt, and very satisfactory recovery, being discharged from the hospital, nearly cured, on February 24th, just a fortnight after the operation. The condition of the urine remained uninfluenced by the severe and long operation.

Regarding the frequency of pneumonia subsequent upon the use of chloroform as an anæsthetic, the reader of this paper can make the following statement: During his activity as surgeon to two hospitals for eight years, only two cases of pneumonia occurred in his practice. Both concerned patients on whom difficult and very bloody operations were performed in the oral cavity on account of cancer of the tongue and floor of the mouth. In one case a considerable portion of the lower jaw had to be removed; in the other one, tracheotomy had to be very hastily performed in the course of the operation, on account of imminent suffocation from the entrance of blood into the trachea. Both patients recovered from the pneumonia, but ultimately succumbed to recurrent cancer.

In both of these cases the entrance of blood into the bronchi was the plausible cause of the pneumonia.

Valvular lesions of the heart cannot in themselves be admitted to form a valid counter-indication to chloroform. As long as the compensation of the valvular trouble by muscular hypertrophy is good, and is so attested by the good quality of the pulse, no hesitation whatever need be felt to give chloroform. It can be positively asserted that the reader of this paper has many times given chloroform in cases where valvular trouble was clearly manifest, without ever observing any untoward accident, or even an alarming deviation from the normal standard of good anæsthesia. Especially where kidney trouble is associated with valvular heart disease chloroform is the proper anæsthetic, not ether, provided that efficient compensation by muscular hypertrophy is attested by the good quality of pulse. As soon as muscular decay by fatty degeneration sets in, chloroform should never be used, as it is much more deadly than ether.

A weak heart, from whatever cause, be it fatty degeneration or great anæmia, or from nervous influences, is the only valid objection to the use of chloroform. The administration of ether is also more than usually dangerous in these conditions, but chloroform certainly is infinitely more so.

Where *fatty changes* of the heart-fibre are present, the fluttering, compressible, and irregular quality of the pulse, together with other clinical aspects of the case in question, will readily warn the careful practitioner against the use of chloroform, and will inspire special caution, even in the use of ether.

Deep anæmia, from various causes, offers no difficulty in the way of its diagnosis, and will also be generally heeded.

In some cases of anæmia, ether, if anæsthesia is not

driven too hard, will even act as a stimulant to the heart's action, as can be attested from actual experience. But carried beyond the point of safety it will cause the same collapse that chloroform would produce.

Functional heart-weakness, produced by nervous influences of permanent or mostly passing character, such as *excessive fear or fright, is, in the estimation of the author, one of the most important counter-indications to the use of chloroform.* It is strange how little stress is laid upon this point by most surgical authors and teachers, although cases of death from fear or sudden fright through heart-failure are not rare in medical literature. Nothing seems more plausible than that a grave depression of the heart's action, by sorrow or fear, should be augmented to absolute syncope by an anæsthetic, especially chloroform. And yet no text-book or monograph is known to the reader of this paper that raises a warning against this contingency.

Few are the men whose quality and rate of pulse remain uninfluenced by the often dramatic developments immediately preceding a bloody operation to be done on their own body.

This, as it were, normal oscillation of the energy of the heart's action is not what is here referred to.

What is meant by fright or excessive fear is an unusual degree of nervous depression, often quite disproportionate to the danger or difficulty of the surgical measure to be taken. The extraction of a tooth, the incision of an abscess, or some similar trivial procedure will, on account of its unexpectedness, perhaps, so overwhelm an ill-balanced or morally untrained nature, that disaster is produced by the additional small depression caused by the anæsthetic. And stress is laid by the authors upon the fact that death from the administration of chloroform is especially common during the performance of small operations.

Great pain, great danger, or long suffering are known to inspire great courage, and consequently death from anæsthetics administered for the performance of great operations is very rare.

It is proper to state, however, that the author has observed many cases of unusual fear, characterized by pallor and a small pulse, in which ether or chloroform being given, the pulse became ostensibly fuller and better as anæsthesia progressed, and everything passed off very well.

Yet his confidence in the sedative effect of chloroform, at least, was very rudely shaken by a sad case of death from its administration.

The case was as follows:

T. E. R——, clerk, aged thirty-two, presented himself, February 10th, at my house, with a doubtful tumor of the right submaxillary region that was non-fluctuating, but apparently of an inflammatory character, as moderate fever was present. A probatory puncture was proposed and acquiesced in, but in attempting it the patient was seized by such an uncontrollable fright that he begged to have chloroform administered. This was declined by me, the proposition being made instead to have him admitted to the German Hospital as a private patient, where, under anæsthesia, the exploration, and such necessary steps as incision or extirpation, might be at once taken as the case might require.

February 15th the patient entered the hospital.

February 17th he was taken to the operating-room, when he expressed to Dr. Wackerhagen, then there present, the conviction that he would not leave the room alive. This I heard of after the accident. The swelling had visibly increased since February 10th, and was clearly fluctuating, undoubtedly a glandular abscess. Dr. Bachmann, the house-surgeon, an experienced and conscientious physician of several years' hospital experience, commenced to administer chloroform in the proper manner, the patient taking the anæsthetic willingly, and even eagerly. Hence respiration was somewhat hurried, but deep and regular. When about two drachms of the anæsthetic had been used on Esmarch's open chloroform mask, he suddenly struck out wildly with his arms, became stiff in opisthotonos, his face turned livid and distorted, the pupils were widely dilated, and it was especially noted that the abdominal muscles were as rigid as a board. The pulse, held from the beginning by Dr. Baughmann, a student of the New York Polyclinic, suddenly ceased, and the patient turned lax and was dead. All this happened within the space of a minute, and all efforts at resuscitation employed for forty-five minutes were of no avail. The patient's heart was carefully examined before the operation by myself and the house-surgeon, and no abnormality was detected. His pulse was of a good quality, except immediately before the two attempts at operative interference, when it was weak and rather rapid. The urine was found normal; in short, there was nothing to sound a warning note. Only the value of the symptom of nervous depression was not justly appreciated in this case, a symptom that had so often been found of no material importance.

The chloroform used was unexceptionable, and was administered in the proper way; hence the coroner's jury exonerated the medical men concerned in the affair. The experience gained in this case has led to the practice, on the part of the author, to freely administer stimulants and a small dose of morphia hypodermatically, preceding anæsthesia, in cases where unusual moral depression is noticeable, and never to give chloroform to a patient subject to excessive fear.

It is fair to assume that ether also may produce deadly effects under such a circumstance. The cases in which anæsthesia must be employed in spite of the presence of fatty heart, or kidney or lung trouble, or where two or all of these conditions are observed, offer unusual difficulties and involve an especial degree of risk. But who would hesitate to perform tracheotomy for a foreign body, or herniotomy in strangulation, though the risks of anæsthesia might be ever so formidable?

As a matter of self-protection a careful physical examination should always precede every operation, if feasible, and the prognosis should be unhesitatingly and truthfully stated to the proper persons, in its entire gravity, before the first stroke of the knife is made. In many cases of great urgency, where deliberation is inadmissible, common-sense and firm decision will be the best guide of him whose readiness to help is not "sicklied o'er by the pale cast of thought."

It may be said, then, as a summary of this essay, that both chloroform and ether, properly administered, are invaluable and useful anæsthetics; that each of them has its proper and legitimate sphere and limitations; that the modern physician is in need of both of them; that unqualified condemnation of chloroform in surgical practice is unscientific and unjustified by the facts; that an intelligent and free selection and employment of either chloroform or ether must be vindicated as a right, and is the duty of every conscientious physician; that fatal accidents occurring in spite of the conscientious employment of the safeguards known to be necessary in selecting and administering either anæsthetic are, however lamentable, not incriminating to the medical attendant; that it is the duty of the teachers in surgery to give practical instruction in the selection and administration both of chloroform and ether.

Trichinosis in Italy.—Dr. Legge, of the University of Camerino, discovered a case of trichinosis in a subject which he was preparing for an anatomical demonstration. The trichinæ were dead and the capsules were for the most part calcified and misshapen. The man had lived for many years in a neighboring commune, and a commission appointed to investigate the case was unable to discover the source of infection. This is thought to be the first case of trichinosis ever observed in Italy.—*Il Raccoglitore Medico.*

CHLOROFORM AND ETHER.[1]

By LEWIS A. SAYRE, M.D.,

NEW YORK.

Mr. President and Gentlemen: I am well aware that my views about anæsthetics, and particularly as to their mode of administration, are entirely at variance with the general teachings of the profession; and yet, from a very extensive experience in their use, I am so thoroughly convinced of the correctness of my views that I continue to maintain them, and put them into practice, in spite of the opposition they have encountered from almost every quarter.

I prefer and almost always use chloroform as an anæsthetic in preference to ether, because it is more agreeable to the patient, more speedy in its effects, does not produce the spasmodic muscular contractions while being administered, and is not followed by the same bad after-effects as ether, such as vomiting, nausea, nephritis, etc.

Mode of administration.—The usual method of administering any anæsthetic, whether ether or chloroform, is to allow *fresh* air—or such as is not impregnated with the anæsthetic—to be inhaled at the same time, thus permitting the *antidote* to anæsthesia to be inhaled at the same time with the anæsthetic, and consequently preventing it from producing its desired and specific results until a much larger quantity has been given than is ever required when properly administered.

The usual plan of pouring into an "inhaler," a prepared "cone," "sponge," or "folded napkin," an *indefinite* amount of either ether or chloroform, and then holding it a *little distance* from the patient's nose and mouth, so that *pure air* may be inhaled along with the anæsthetic, and every few minutes pouring on an ounce or two more, *without any accurate measurement*, is, in my opinion, decidedly wrong.

We certainly do not use arsenic, strychnine, corrosive sublimate, prussic acid, or any other potent agent in the same reckless way; but are very careful to measure, with great exactness, the precise number of drops or grains that we know is the maximum dose that the human system can bear with impunity. Chloroform and ether are both powerful agents—each of them has caused many deaths, as the records of our different medical journals abundantly prove—and I therefore think that they should be used with the same careful skill in *measuring* the dose that we would use in the employment of any other potent drug.

The inhaler I here show you was made for me many years ago by Mr. Reynders, after a pattern of Leur, of Paris, and I have found it very efficacious in producing rapid anæsthesia, because it excludes all air except such as is impregnated with the anæsthetic.

I suppose you are all familiar with the instrument, as it has been in the market for many years; it is simply a German-silver cup to place over the mouth and nose, with a notch in its upper border to fit over the latter organ. A wire gauze is placed across the lower half of the cup, at about its centre, and behind this is to be placed the sponge to hold the anæsthetic. Beneath the sponge is an opening for the *admission* of air on *in*halation, and opposite the mouth is another opening for the *expulsion* of the air on *ex*halation. These openings are alternately opened and closed at each inspiration by the small wooden balls which act as valves in the instrument, so that no air can be inhaled except such as passes through the impregnated sponge, and the impure air is exhaled through the upper opening.

In some cases the instrument would not fit with sufficient accuracy to prevent the air from coming in between the nose and cheek without pressing the inhaler so hard upon the face as to cause the patient some inconvenience, and my son, the late Charles H. H. Sayre, modified the instrument by placing around its border this india-rubber bag, which can be inflated from a small tube connected with it, thus making a soft, elastic air-cushion, which can be pressed down upon the face so firmly as to make it absolutely air-tight without any inconvenience. Consequently no air is inhaled except such as comes through the lower opening, and must therefore pass through the sponge which has been impregnated with the anæsthetic.

Ten, twenty, or thirty drops of chloroform, administered in this manner, will almost invariably produce anæsthesia by a very few inhalations, and if by any peculiar predisposition, or some other unknown cause, the heart should cease to act, a few artificial inspirations will eliminate this small quantity of the anæsthetic and thus restore the circulation and save the patient. Whereas, if the anæsthetic had been administered in the usual way and a large amount had been inhaled, and the whole system saturated with it—if, under such circumstances, the collapse occurs, it sometimes happens that even the most vigorous efforts have failed in producing resuscitation.

I have practised this method for many years, and taught the same in all my clinical lectures, some of which have been published by different medical students in various medical journals; but I cannot at this moment refer to any one in particular where a full account of my method has been published. But in the "Transactions of the International Medical Congress," held in Philadelphia in 1876, and published in 1877, will be found a full account of my demonstration of the treatment of hip-disease at the Pennsylvania Hospital, before the Congress.

Just at the conclusion of my demonstration a child was brought into the lecture-room in the advanced third stage of the disease.

A consultation was immediately held with Mr. Adams, of London; Professor Lister, of Edinburgh; Professor Hueter, of Greifswalde; Professor Hjort, of Christiania; Professor Hingston, of Montreal; Professor Post, of New York, and others, and exsection of the hip-joint was decided upon as the only chance for recovery; and on page 594 of these Transactions I find the following record of my remarks made at that time, and taken down by the stenographer:

"While chloroform was administered by Dr. Sayre's son, Dr. Sayre said that his plan of using chloroform was entirely at variance with that taught in the books, and with the doctrine of most authorities, viz., that air must be inhaled with the anæsthetic. Air, he said, was the antidote to the anæsthetic, and as long as it was introduced anæsthesia would be prevented; he therefore carefully excluded all air not saturated with chloroform, and found that ten, fifteen, or twenty drops thus administered, according to the age of the patient, produced prompt anæsthesia without that muscular resistance and contortion of the body which followed its administration when mixed with air.

"If, by any possible contingency, this small quantity should produce dangerous or unpleasant symptoms, a few artificial respirations, effected by compressing the chest, would exhale the small quantity of poison and thus avoid any fatal result. When chloroform was given in the usual way, *i.e.*, mixed with air, anæsthesia was not produced until a large quantity had been inhaled, in some cases many ounces, the patient during this time struggling violently; and the damage done to an inflamed joint by these struggles more than counterbalanced the good from the anæsthetic. If, under these circumstances, failure of the heart or respiratory organs took place, the system was so saturated with the chloroform that resuscitation by artificial means was almost impossible.

"The administration of the drug in the present instance confirmed the correctness of Dr. Sayre's statements."

I must apologize, Mr. President, for making this long

[1] Remarks made before the New York Academy of Medicine, April 7, 1887, on Dr. Gerster's paper.

quotation; but I have done it to show that the views I have expressed here to-night are not of recent date, but have stood the test of many years' careful observation, and personal experience—and although they have been thus publicly expressed for many years they have not been generally adopted, and I am therefore very much obliged for this opportunity of bringing them to the notice of the representative members of our profession gathered here to-night, and hope that at least they will have the effect of eliciting some discussion on this most important subject.

THE RELATION OF LARYNGEAL TO PULMONARY PHTHISIS, AND THE IMPORTANCE OF LOCAL TREATMENT.[1]

By CLARENCE C. RICE, M.D.,

PROFESSOR OF DISEASES OF THE NOSE AND THROAT, POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

About one-fourth of all death-certificates bear the name pulmonary phthisis, and statistics show that in about one-third of this number the larynx is involved in a similar process of inflammatory degeneration, so that one-twelfth of all our patients suffer from the disease called laryngeal phthisis. But even this fact would not be a sufficient excuse for appropriating any of the valuable time of this Society for the purpose of adding anything to the much that has been said here and elsewhere about this disease, were it not that I believe that but a small percentage of the cases of laryngeal phthisis ever receive either special, general, or local treatment at the hands of the practitioner of medicine. I arrived at this conclusion after questioning a number of prominent physicians in this and other States, who have told me that they paid no special attention to the laryngeal symptoms of consumption, treating them only in the general way of tonics, good feeding, etc. Upon *this* condition of affairs something may with propriety be said.

If any gentleman would unlearn the little that is positively known concerning the etiology and pathology of laryngeal phthisis, he should read the various opinions advanced by different writers; and allow me to quote from a few of these. The subject of laryngeal phthisis received but little intelligent attention until Laënnec,[2] in 1819, strongly asserted the tubercular nature of the disease. Louis[3] soon after disputed this point, and contended that the inflammation was simple in character and the ulcerations were due to the corroding effect of the sputa. Cruveilhier and Trousseau agreed with him substantially. Rheiner[4] thought that attrition of the soft parts of the larynx, brought about by the incessant cough, was a sufficient cause for the ulceration. Schottelius believed that the inter-arytenoid ulcerations were usually caused by friction and were simple in character, although he admitted that there may be secondary tubercular deposits. Rindfleisch[5] says that phthisical ulceration commences at the mouths of the glands of the larynx and is frequently a purulent follicular catarrh, causing ulceration because of the existing "strumous diathesis." Hastings,[6] of London, and Horace Green, of New York, thought this process in the larynx more often associated with, and dependent upon, the existing chronic pharyngitis than upon pulmonary consumption. Von Ziemssen[7] evidently believes that the ulcerations so frequently present in laryngeal phthisis are not always of the same character, and he mentions these varieties: First, ulcerations due to degeneration of tubercle; second, follicular ulcerations caused, as Rindfleisch says, by a purulent follicular catarrh; third, ulcerations due neither to deposit of tubercle nor to ulcerated follicles, but to an infiltration of the sub-epithelial layer of the mucous membrane with cells and nuclei, the ulceration being mainly brought about by the unceasing motion of the larynx; and a fourth form is the erosion of the aphthous ulcer, very superficial, and to be found near the deep true tuberculous ulcer. These aphthous ulcers, Von Ziemssen believes, as did Louis, are caused by the infection of the corroding secretions; but Von Ziemssen does not believe that they are simple in character, but are, on the other hand, peculiar to pulmonary phthisis. Türck, without formulating his convictions as to the etiology of laryngeal disease, speaks guardedly of the "laryngeal diseases standing in connection with pulmonary tuberculosis." Virchow[1] and Rokitansky[2] contend for laryngeal tubercle; and Virchow believes the larynx to be particularly predisposed to the deposition of tubercle, and the deposit, as a rule, so superficial that it quickly degenerates into an ulcerative process by reason of the functional activity of the larynx.

Schnitzler finds the cause of the disease to be a simple chronic inflammation of the mucous membrane, and the ulcerations due to a follicular tumefaction. While Heinze,[3] in a very valuable paper, the result of laborious research, states that all laryngeal phthisis is tuberculous and secondary to pulmonary manifestations. Stoerck, Isombert, and Wendt agree with him. Mackenzie,[4] of London, whose large clinical experience gives great weight to his writings, defines laryngeal phthisis as a chronic affection of the larynx arising from the local deposit of tubercle. This author quotes frequently from Heinze, and seems to be in full accord with him. On the other hand, some of our American writers who, too, have seen and treated numerous cases of laryngeal phthisis, believe that the deposit of tubercle is not, in the majority of instances, the primary lesion in consumption of the larynx. Careful observation has taught them that there is little that is peculiar about the disease. It has commenced like a simple catarrhal inflammation, and has continued like one. Dr. Beverley Robinson[5] says that, "ulcerative phthisical laryngitis is certainly not tuberculous in the great majority of instances, and hence, in my opinion, is susceptible of cure." Dr. Francke H. Bosworth[6] expresses the opinion that, "laryngeal phthisis is not necessarily of tubercular origin primarily, but of inflammatory origin; and that if tubercles are found on autopsy, they are the gray nodules which are frequently found about the base of any chronic ulcerative disease;" and he adds that, "in the early stages the disease is curable in probably the majority of cases." Porter,[7] of St. Louis, also speaks very hopefully of the prognosis in these cases when they are treated properly at an early stage.

At the present time it is admitted by nearly everyone that, in the great majority of instances, laryngeal phthisis occurs secondarily to pulmonary phthisis, and is occasioned by the same predisposing causes which lie at the foundation of the etiology of pulmonary consumption. When the disputed points in regard to the part which tubercle and tubercular bacilli play in the causation of lung-disease are settled, much light will be thrown upon the character of this process which attacks the larynx. Many, and most writers at the present time, give the name of the disease under consideration as tubercular or tuberculous laryngitis, discarding altogether the older name—laryngeal phthisis. Others use the terms synonymously and indiscriminately. The discussion as to whether tuberculosis ever occurs primarily in the larynx, that is, before its appearance in any other portion of the body, is not an important one to this paper. Some few cases are recorded. The diagnoses have been based on the fact that

what are supposed to be the typical appearances of deposit and degeneration of tubercle have been seen by authentic observers to occur in the larynx at a period when most careful examination failed to discover any such condition of the lungs. These patients, however, developed pulmonary tuberculosis soon after. I presume that it is the general opinion that when the tubercular infiltration was first noticed in the larynx a similar deposit had already taken place in the lungs, although it did not furnish tangible physical signs. Leaving the question of primary laryngeal tuberculosis out of consideration, we come to a far more important part of our subject, and these questions present themselves :

Is laryngeal phthisis always tubercular phthisis ? and if so, is the deposit of tubercle always the primary lesion of the larynx? or is the deposit oftentimes secondary to a catarrhal laryngitis of simple character which, aggravated by the bad general condition of the patient, has gone on to the stage of ulceration ? And, again, granted that tubercular tissue is deposited in the larynx at an early or later period, is it the cause of the degenerative process that follows? does its presence render the disease called laryngeal phthisis a specific one, that is, totally unlike a simple catarrhal process ? or, on the other hand, is not the deposit of tubercle one of the later manifestations of an ordinary chronic catarrhal laryngitis? Heinze, who, as has been said, has been one of the most radical believers in the tubercular origin of phthisical laryngitis, could demonstrate the presence of tubercle microscopically in only one-half his cases. What shall be said of the remaining fifty per cent. ? That secondary tubercular deposit in the larynx is a very common sequel to pulmonary phthisis there is little doubt, and I believe that it is equally true that oftentimes this infiltration takes place at a comparatively late period of the disease, the symptoms, cough, hoarseness, aphonia, painful deglutition, etc., being due for a time to an aggravated simple catarrhal laryngitis. That many such larynges show nothing more than the lesions of an ordinary catarrhal process I have demonstrated to my own satisfaction many times.

Two extreme beliefs, then, in regard to the pathology of laryngeal phthisis, are held—the first, and most generally credited one, being that the inflammatory process in the larynx is always due to the deposition of tubercle, and occurring after the same condition has taken place in the lungs. The second opinion, to which a gradually diminishing number still pin their faith, is that tubercle plays but a very inferior part in the etiology of the laryngeal inflammation, and in the small percentage of cases where tubercular infiltration is found it is supposed to have involved the larynx after the stage of ulceration had been reached. Neither of these theories seem to me to be so fully supported by laryngoscopic and clinical investigations as one somewhat between the two. Like most disputed points in medical science, the whole truth is not to be found on either side. That tubercular laryngitis is not an inappropriate name for the disease under consideration is proven by the careful studies made by such men as Virchow, Rokitansky, Heinze, and Mackenzie. They all agree as to the presence of tuberculous tissue, but, as Dr. Alfred L. Loomis says, while " all observers agree as to microscopical *appearance*—in their *interpretation* they differ widely. An etiology of any disease which is built up on post-mortem pathological appearances may not explain all the phases of a disease. The microscope does not supplant the clinical investigator, and so we say that, while tubercular infiltration is known to be present in many cases of laryngeal phthisis, its presence does not imply a disease which runs a typical course or one in which the prognosis is always bad. Medical observers whose opinions have been formed mainly by *laryngoscopical examinations* of these cases still cling to the belief that many cases of laryngeal phthisis are not in any way peculiar in character, but are the result of a simple catarrhal inflammation which has reached the unusual stage of ulceration and degeneration only because the general condition of the patient tends so strongly to the formation of unstable lymphoid tissues, and because there is so little general recuperative power. These men claim, also, that laryngeal phthisis occurs as a complication of Bright's disease, syphilis, scrofula, etc., and is a sequel to *non*-tubercular as well as tubercular phthisis. While we think it would be difficult to prove that phthisis of the larynx ever occurred as the result of the asthenic condition produced by Bright's disease and syphilis, unless these conditions had also led to pulmonary degeneration, we do believe that there are many cases of so-called tubercular phthisis which do not present the characteristic laryngoscopical appearance ascribed to that disease, and which strongly support the opinion that the disease is frequently a simple catarrhal one.

You are all familiar with the appearances of the larynx which are considered pathognomonic, the pale color of the mucous membrane, the thickened turban-shaped epiglottis, the swollen club-shaped arytenoid cartilages, and the inter-arytenoid thickening. This tumefaction of the epiglottis and arytenoids is peculiar. There is nothing like it found in any other variety of laryngitis, and when it is present there would seem to be no question but that this characteristic swelling is due either to the deposition of the so-called tubercular tissue or to the infiltration of a tissue not to be found in simple catarrhal inflammation. Upon these appearances I believe that a positive diagnosis of incipient pulmonary phthisis can be made, even though no evidence of lung-change can be found, and I consider the differential diagnosis of this disease from any other variety of laryngitis based on *these appearances* as extremely simple. I mean, when all these appearances are present, or even when the epiglottis and the arytenoids are both involved in this peculiar swelling, tumefaction of the arytenoids alone, without inter-arytenoid change, does not make the diagnosis certain. There is, however, a class of cases of laryngeal phthisis, and they are not so infrequent, which present none of the characteristic tumefactions of laryngeal phthisis ; in fact, they differ not at all in their laryngoscopical appearances, certainly not in their early stage, from the ordinary cases of subacute and chronic catarrhal laryngitis. Nor do they differ in their later and latest stages, unless ulceration may be said to be foreign to simple catarrhs and due only to specific inflammations, for ulceration is the only distinguishing feature.

A word as to the local causes which greatly tend to aggravate a simple catarrh of the larynx and to produce ulcerations where there exists a predisposition to pulmonary phthisis.

It must not be lost sight of that the physiological function of the larynx is a grave predisposing cause to inflammation of the mucous membrane here—a part that is put in motion with every breath, that undergoes friction with every word spoken, and that is constantly exposed, not only to sudden and marked changes in the temperature of the air which comes in contact with it, but also to dirt, dust, and foreign bodies generally—such a portion of the body cannot long retain its integrity when there are added to these irritants the mechanical violence of a harassing cough and the infecting irritation of decomposed tissues which pass over it constantly from the lungs. This condition of affairs alone is, to my mind, sufficient reason for the frequency of phthisical laryngitis, and explains the tendency to ulceration in this disease. To prove that the function of the larynx is not a theoretical predisposing cause of inflammation, let me state this significant fact, viz., that, by reason of the greater stress upon the vocal organs and the greater exposure to rough weather, phthisical laryngitis occurs about twice as frequently in males as in females, whereas pulmonary phthisis occurs about equally in the sexes ; and just here there is a valuable suggestion as to the treatment of this disease, viz., to obtain complete rest for the larynx by not using the voice.

Those who have made much study of inflammatory conditions of the upper respiratory tract know to-day, as they did not know three years ago, the very intimate relation which exists between nasal and post-nasal catarrhs and inflammation of the larynx and the lungs. If you would cure a laryngitis, you must first cure the nasal disease which has occasioned it; and it is not too much to predict that pulmonary and laryngeal phthisis will become less and less frequent as obstructive nasal diseases are more successfully treated.

Tubercular laryngitis is an unfortunate name for a disease which is not always tuberculous, because the majority of medical men think that tuberculosis is as little amenable to treatment as carcinoma. And for that reason it is highly important to classify the cases of laryngeal phthisis according to the process which can, by laryngoscopical examination, be seen to be present. To formulate my belief more concisely, I would say that I believe that laryngeal phthisis is not always laryngeal tuberculosis. That in about sixty-five per cent. of the cases we find the characteristic tumefaction due to the deposition of tubercle, but in the remaining thirty-five per cent. the process is slow and insidious, commencing with an ordinary subacute catarrh, which becomes chronic and finally ulcerative when the condition of the patient has become impaired. The prognosis will depend upon the stage at which the disease is recognized and treated.

I most earnestly bespeak for these cases the benefits to be derived from local treatment—topical applications. Time and time again, when these cases have presented themselves early, I have seen the hacking cough checked as soon as the subacute laryngitis was relieved; and so, for the time at least, any progress of the laryngeal phthisis was prevented. I have seen many cases where the arytenoids presented the typical club-shape swellings improve rapidly under local treatment, and a number have been cured when the stage of ulceration had been reached. In these cases the larynx, perhaps, more than the lungs is the seat of the cough-producing irritant, and when the cough is checked one very depressing factor is removed. And if by local treatment—and it is the only reasonable way of controlling this distressing symptom, painful deglutition—this can be relieved, there is some hope of strengthening the patient by proper nourishment. I know that busy practitioners throughout the country have little time to devote to the study of laryngology, but it is the duty of every man who treats laryngeal phthisis to become sufficiently skilful with the laryngoscope to be able to detect the early evidences of this disease, and to carry the laryngeal applicator or direct atomized fluids or medicated powders into the larynx. A laryngeal mirror, an applicator, or a hand-bulb atomizer, or a powder-blower, with some simple illuminating apparatus, is the necessary equipment.

Be suspicious of any long-continued hacking cough—such a case should have the benefit of a laryngoscopic examination at once; and if a very pale larynx is seen, or if there is inter-arytenoid thickening, the lung will soon show evidences of disease unless the larynx is treated and the proper attention paid to the general health of the patient. The larynx frequently gives unmistakable signs of approaching pulmonary phthisis months before the lungs show any evidences of it.

I shall not attempt to enumerate all the different local remedies that have been employed in laryngeal phthisis, but will mention a few which are easy of application, and upon which I have placed most dependence. Dr. F. H. Bosworth, in his excellent article on laryngeal phthisis, covers the important points of successful treatment: First, by insisting that the parts be thoroughly cleansed with a mild alkaline and disinfecting spray before the medication is applied; and second, that some anodyne be employed before or incorporated with the astringent or alterative to be used, so that whatever benefit may be derived from the medicament may not be lost by paroxysms of coughing and vomiting. It will answer the purpose as well, and save trouble, if hydrochlorate of cocaine be added to the preparatory cleansing spray, and I have used this formula with success:

℞. Sodii bicarbonatis,
Sodii biboratis ..... āā grs. v.
Cocaine hydrochloratis ..... grs. vii.
Listerine,
Glycerinæ..... āā ʒ j.
Aquæ destil..... ad ℥ j.

M. Sig.—Spray into the larynx five minutes before making the principal application to the throat.

This should be sprayed into the larynx with a hand-bulb spray, and also above into the post-nasal space. The laryngoscope is not needed for this. The cocaine may be omitted, using the above formula only for cleansing purposes, and it may be followed by a solution containing five grains each of sulphate of morphia and bicarbonate of soda to the ounce of water. Eight minutes later, when the cocaine or morphia has produced local anæsthesia, the principal application can be made. I agree with those men who believe that iodoform has a specific effect in laryngeal phthisis. Better results can be obtained with it than with silver, copper, zinc, or any of the astringents I am in the habit of applying iodoform in solution in ether with a soft wad of absorbent cotton wound about a small applicator. It is not more irritating than the powder, and the rapid evaporation of the ether gratefully cools the inflamed larynx. The application is to be made very gently. If the physician cannot use the laryngeal applicator he may, with a powder-blower, employ the following:

℞. Acidi tannici,
Acidi boracis..... āā ʒ j.
Iodoformis..... ʒ vj.

M. Sig.—Blow a small quantity into the larynx with powder-blower.

Rest to the larynx—obtained by not speaking above a whisper—wearing a respirator in cold or dusty weather are important points. Spraying a two per cent. solution of cocaine or one-eighth of a grain of morphine into the larynx just before the patient eats affords great relief. Tracheotomy as a means of securing rest to the larynx I do not think deserves serious consideration. It is frequently desirable, when deglutition is painful on account of ulcerations of the larynx, to obtain rest for the parts by feeding with, not the stomach-pipe, but the œsophageal tube.

In conclusion, I would say that I believe that the early cough in pulmonary phthisis is due quite as much to laryngeal as to pulmonary irritation. I believe, too, that the laryngeal catarrh hastens the degenerative process in the lungs. I also believe that appropriate local treatment to the larynx will often cure laryngeal phthisis in its early stages and afford much relief after ulceration has taken place.

Almén's Test for Sugar in the Urine.—Dr. K. A. Norderling, of Rockford, Ill., in referring to the defects of Trommer's test for saccharine urine, sends the formula proposed by Professor Almén, of Upsala, which, he says, possesses many advantages. It is reliable, and will keep unchanged for years. The following is the formula:

℞. Caustic soda, Gm. 8 (ʒ ij.) in water..Gm. 100 (℥ iij.)
Potassio-sodium tartrate.....Gm. 4 (ʒ iv.)
Bismuth subnitrate.....Gm. 2 (ʒ ss.)

The urine is first to be tested by heat and nitric acid for albumen, and, if any is present, it is to be separated by filtration. In testing for sugar, one part of the solution is used to ten parts of urine. By means of this bismuth solution, Dr. Norderling affirms, sugar may be detected when present in the proportion of only .05 per cent. The preparation of the solution should be intrusted only to a competent chemist.

TWO CASES OF INSUFFICIENCY OF THE SUPERIOR RECTUS MUSCLE, WITH DISTRESSING SYMPTOMS PERMANENTLY RELIEVED BY PRISMS.

By R. W. AMIDON, A.M., M.D.,

[NEW YORK.]

It is with extreme diffidence that I present these two cases, as they were not studied with the care their rarity deserved, or with that mathematical precision the science of ophthalmology is capable of. Both patients came to me in the course of neurological practice for the relief of nervous symptoms. In both, on being submitted to a routine examination, these symptoms were found to be of ocular origin. And if the examination ot the cases now seems faulty and its record lacking in detail, let the apology be that the examination sufficed to locate the mischief, and what is still more important, particularly to the patient, to remedy it.

Case I.—A gentleman aged sixty-two first consulted me, January 5, 1880. He was an officer in a bank and had for years done much near work with his eyes. Naturally, or by occupation, he was of a rather weak muscular and irritable nervous constitution. His digestive power was feeble, often failing almost entirely. His chief trouble had been, for years, frequently recurring attacks of headache starting from the left occiput, running forward over the head to the left brow, and often going across the forehead to the right brow. These attacks usually terminated in profound nausea, vomiting, and extreme prostration, and were generally followed by a sick spell characterized by aggravated indigestion and flatulent dyspepsia. He always was below par and had abused his eyes before attacks came on.

His vision was $\frac{6}{10}$ with each and both eyes; with a +.50 D. it was $\frac{6}{6}$. He had insufficiency of the interni, 4° for distant and 7° for near vision. His accommodation had practically disappeared. His fundus oculi was normal.

An examination two days later showed the same state of affairs, and he was ordered, in addition to the +3 D. which he was then wearing, a prism of 2.5° base in over each eye.

Because of a nervous feeling which spectacle-frames gave him he was reluctantly allowed to wear eye-glasses. He was made very comfortable for almost six years with these glasses or similar ones, the spherical remaining the same and the prisms varying in strength according to the amount of insufficiency, which was constantly present, but variable in degree. During this time the insufficiency of the interni for distant vision varied from 2° to 5°, the average of thirteen observations being $3\frac{1}{4}$°, while for near vision it varied from 5° to 16°, the average of fourteen observations being $8\frac{1}{3}$°. During this period he complained to me of but few *bad* headaches, his general health occasionally calling for a short course of bitter tonics with iron or an alkali.

In December, 1885, having presumably the same insufficiency I never saw him without, he consulted, without my knowledge, an oculist who told him that only cutting the muscles could relieve him, and who ordered for him +75 S. and a prism of $1\frac{1}{2}$° base out over each eye for constant use for the distance. He wore them a few hours, but they gave him a violent sick headache. When he was able to go out again he consulted me again and I found, December 17, 1885, that he had an insufficiency of the interni for the distance of 2°, for near vision of 6°, and I ordered him +3 S. and a prism of 2° base in over each eye. These rendered good service until July 13, 1886, when, on his return from Europe in poor health, he called, saying his eyes troubled him a good deal and he wanted to try spectacles. At this time his insufficiency was 3° far and 5° near, and as his presbyopia had increased I ordered him +3.50 S. and a prism 2° base in over each eye, also a tonic of nux vomica, quassia, and quinine. He remained well up to December, 1886, when he consulted another oculist, who said he did not need prisms, and ordered him +1 S. for distance and +3.50 for reading. He found he could get along with the distance glasses, but with the others he could not see at all. He came back to me, December 28th, just recovering from a violent left hemicrania and bad gastric attack brought on by the use of the simple spherical glasses. He was very much run down. The insufficiency of his interni was for distance 2°, for near 6°. No insufficiency of the interni for the distance showed itself without a deflecting prism, but with a red glass over the left eye the red image appeared above and to the right of the white at an angle of 45°, and not more than two inches distant. This false image was made to coalesce with the true image by the use of a prism of 2° base up and in over the left eye, or the same prism base down and in over the right. This result was repeatedly obtained, but at the end of the examination it was found that this vertical diplopia had disappeared.

I ordered him to cover the left eye during work, take a capsule containing extract of nux vomica .02, extract of quassia .10, quinine .12, and reduced iron .15 before each meal, and report in a week.

January 4, 1887, his insufficiency for distance was 4°, for near was 6°. The vertical diplopia was again detected by the use of the red glass. It was corrected by the use of a prism of 2°, placed at an angle of 145° base in over the left eye, or the same prism at an angle of 145° base in over the right eye.

When the insufficiency of his interni was corrected a prism of 2° base up over the left eye or base down over the right eye, corrected his vertical displacement completely. As he referred most of his trouble to his left eye I ordered him spectacles +3.50 S. over each eye with a prism of 3° base in over the right eye, and a prism of 2° base up over the left eye. Twice since then I have seen him and he expressed perfect satisfaction with the glasses. In this case all ocular movements to gross tests were normal except near convergence. He had no ptosis nor squint, nor did he hold his head back. The tests were made in the horizontal visual plane and the patient spoke of no obliquity of the false image.

The ultimate result will be, I expect, a cure of the insufficiency of the superior rectus as occurred in my second case. It may be interesting to know that a brother of this patient, two years younger, consulted me recently, and I found he had compound myopic astigmatism in one eye, compound hyperopic astigmatism in the other, and presbyopia of both.

Case II.—The patient was a physician, thirty-five years old. He was in poor general health, hard-worked, and had suffered losses in his family. He had begun the use of convex glasses years ago. For many years his eyes had troubled him, and he had attacks of vertigo which caused him to stagger and necessitated the constant use of a stout cane.

February 17, 1880, he had a severe attack of vertigo, with projection forward. He fell on the street. After this attack he felt very weak. Has had some frontal and bitemporal headache after using eyes. For a short time before coming to me he had diplopia, with elevation of one of the images.

He consulted me, giving the foregoing history, February 21, 1880. An ophthalmoscopic examination revealed nothing except slight hypermetropia and astigmatism. His range of accommodation was normal. There was slight insufficiency of the interni to the prism test, and the vision was made normally acute by the use of weak convex cylindrics, axis 90°. These were ordered for him and helped him somewhat, but he suffered occasionally from vertigo and still noticed the vertical diplopia.

March 4, he consulted me complaining still of the vertigo and diplopia.

The insufficiency of his interni for the distance was 2° ;

for near vision 4°; while it was found that the vertical diplopia was relieved by a prism of — 2° base up over the left eye, or the same prism base down over the right eye. Upon subsequent examination it was found that by tilting the prism of 4° base in, which corrected the insufficiency of his interni to an angle of 160°, over either eye it corrected the insufficiency of his superior rectus as well as a prism placed vertically. Such being the case I ordered him + 1.25 cyl., axis 90°, with a prism of 4°, angle 160°, base in over the right eye, and + 1 cyl., axis 90°, over the left eye.

For three years he wore these glasses continuously, suffering from no vertigo or diplopia, and entirely discarding the use of a cane, which before had been indispensable to his security in walking.

He called to see me, February 8, 1883, having worn out the frames of his glasses. On examination I then found that his vision was, R. eye, $\frac{6}{\frac{1}{3}}$ w + 1.25 cyl., ax. 80° = $\frac{6}{6}$. L. eye, $\frac{6}{\frac{2}{3}}$ w + 1.25 cyl., ax. 90° = $\frac{6}{6}$. He had an insufficiency of the interni of 2° for near vision, of 4° for distant vision. The insufficiency of the superior rectus had disappeared. I simply prescribed for his astigmatism eye-glasses which continued to give him satisfaction for over two years, when he died of phthisis while South.

A younger brother of this patient consulted me in 1882, and I found him the victim of compound myopic astigmatism and insufficiency of the externi.

Two cases very similar to mine are reported by W. A. Brailey, M.D., in the "Transactions of the Ophthalmological Society of the United Kingdom for 1883," p. 288, and 1881, p. 188.

THE EPILEPTIC COLONY AT BIELEFELD.

By FREDERICK PETERSON, M.D.,

FIRST ASSISTANT PHYSICIAN HUDSON RIVER STATE HOSPITAL, POUGHKEEPSIE, N. Y.

A short time ago I visited the "Bethel" Epileptic Colony, at Bielefeld, in the province of Westphalia, Germany. It is now nearly twenty years since Pastor von Bodelschwingh, a Lutheran clergyman, purchased a farmhouse, and with four epileptics established here a colony which, for nobility of conception and successful results, has nowhere an equal. From this small beginning there has been a gradual growth until to-day there are over eight hundred and twenty-five epileptic patients, and more than sixty houses upon the farm. The founder had long considered the unhappy lot of these unfortunates, who are usually burdens to their families, against whom the public schools are closed, whom none will employ in shops or apprentice to trades, and who are often necessarily deprived of social intercourse with their fellows by the nature of their malady, or find an asylum only in institutions for idiots or insane. It seemed to him feasible to create a refuge where these sufferers might be cured if curable, might have a home if recovery were impossible, might learn trades, and the great majority become educated, useful, and industrious citizens. Visitors are deeply impressed with the happiness, contentment, and prosperity everywhere apparent among the inhabitants of this little epileptic world. No longer an experiment, it answers the previously unanswerable objections to such aggregations. Since its foundation more than two thousand patients have been treated here, more than one hundred and fifty cured, and more than four hundred and fifty discharged improved.

The employments in this institution are numerous and varied. Work not only ameliorates the mental and physical condition of epileptics, but the incurably afflicted are provided with occupations which they are not permitted elsewhere to follow.

A school furnishes instruction to some one hundred and fifty pupils of both sexes. All branches are taught.

The dairy and the farm and garden require the attention of the greatest number of patients, especially as a large trade in vegetable and flower seeds is carried on by the colony.

Among the shops for epileptic workmen are those for carpenters, cabinet-makers, painters and varnishers, printers, bookbinders, blacksmiths and foundrymen, tailors, and shoemakers, and among the stores are a grocery, a pharmacy, a seed-, and a book-store. The carpenters aid in the building and furnishing of new houses. Books are printed and bound and sold here, especially popular works for religious and moral instruction (the colony being under the patronage of the Lutheran Church). Plans and drawings for new buildings are made in the architects' room. Chromos and photographs of a religious or patriotic character are dealt in. The illumination of mottoes for hospital wards and school-rooms, and the coloring of picture-cards are features of the work performed.

Washing, cooking, knitting, sewing, and fancy work employ many.

From the drug department over twenty thousand ounces of bromide of potash are annually distributed free of charge to epileptics anywhere in the world who are unable to pay for the drug, and who apply here for it; while four times that quantity is sent out yearly in twenty-gramme powders to any who pay the wholesale cost-price. Lately a bureau has been added for the collection and sale of museum objects, such as antiquities, articles of ethnographic or historical interest, autographs of distinguished people, coins, stamps, bronzes, gems, engravings, etc., and specimens from the Animal, Vegetable, and Mineral Kingdoms. From this brief outline it will be seen how every effort is made to multiply and vary the pursuits according to the tastes of the colonists. For men alone there are now nearly thirty different callings.

Every shop and school has a mattress or bed conveniently at hand in case of emergency. Several physicians of the town of Bielefeld visit the institution and oversee the medical treatment.

The whole establishment is, of course, on the cottage plan. The houses exhibit great diversity of architecture and position, and are well separated, with large gardens around them, as are the houses in some country villages.

Not the least interesting feature of the colony, which I can but mention in this place, is the training-school for nurses, which has existed many years. Here healthy, well-educated men and women, usually of the higher German classes, who are inclined to devote themselves to eleemosynary work from religious motives, are trained in general nursing and especially in the care of the insane. Several German asylums are wholly supplied with brothers and deaconesses from this institution to care for their patients. Five years is the time allotted to training.

The entire establishment, with its corps of instructors in schools and industrial pursuits, its nurses in training, its epileptics, and its officers, numbers some fifteen hundred inhabitants. It is growing constantly, with an increase that cannot be checked. Patients come from many parts of Europe and from different States in this country.

The result of years of experience with a large number of cases has led to the adoption of the following general plan

Employment for mind and body.—This is paramount. Out-door work is best.

Diet restrictions.—Food must be plain, not rich, and little acid. Spirituous liquors are to be avoided. Coffee and tea must be weak and mixed with much milk. (Smoking allowed in moderation.) A good milk-diet is preferable to meats or soups. Supper should be early and light.

Baths.—Cold shower-baths gradually prolonged and cold sponge-baths are beneficial.

Drugs.—The most effectual remedy is the bromide of potassium. It has more value than any other bromide.

It can be taken for years without deranging the stomach. It cures some cases, it lessens the frequency of seizures in others, it soothes the nerves, it often prevents imbecility, it sometimes tends to strengthen the mental faculties, especially the memory. The prescription is as follows:

℞. Potassii bromidi.. 20 grammes (ʒ v.).
Aquæ puræ..... 200 " (ʒ vj.).

Sig.—Take one tablespoonful three times daily, half an hour before each meal for the first week; four times daily at equal intervals (always some time before or after meals) the second week; five times daily the third week; and so on until eight tablespoonfuls are taken daily, which limit should not be exceeded.

Drowsiness, heaviness, wide-spread skin-eruptions, etc., indicate the necessity of decreasing the dose for a time.

The above dosage is for patients over sixteen years of age From ten to sixteen years, begin with three tablespoonfuls, but do not exceed five or six. Under ten years, begin with two daily and increase to four or five. Very young children should be given still less.

The drug as generally sold contains five to six per cent. of chlorate of potash and other foreign ingredients. An effort should be made to procure a purer drug than this. For this colony a bromide of potash is specially prepared which contains but 0.5 to 0.7 per cent. of foreign matter. The agent should be continued in gradually diminishing doses after the cessation of the disease, even for as long a period as eight or nine months.

Circulars in German and English, embodying the above method of treatment, are sent the world over to epileptics.

There is one small building in this colony set aside for cases periodically or mildly insane; but the worst cases of epileptic insanity are sent to lunatic asylums.

Other colonies upon this model have recently been founded in several Prussian provinces, in Saxony, in Würtemberg, in Switzerland, and in Holland.

The creative genius of this place, the Pastor von Bodelschwingh, whose large philanthropy has alleviated the condition of over two thousand wretched sufferers here, and many more in the outside world, without regard to religious sect or country, expressed to me the hope that the people of the United States or their legislatures would soon seek in some similar or better manner to mitigate the misfortunes of their one hundred thousand or more epileptics.

New York has probably twelve thousand epileptics.[1] Over one hundred and fifty are annually *admitted* into her lunatic asylums—not to count those already there for years—most of whom should and could be better treated elsewhere.

Why should New York not take the lead?

The Expense of Quackery.—There are in San Francisco, says the *Pacific Record*, one hundred and twenty-five illegal practitioners—*i.e.*, those whose ignorance is so appalling that they could not obtain a license from any of the examining boards. In the State there are over five hundred of this class. Some of them spend large sums monthly for advertising. We know of one whose advertising bills are two thousand dollars a month. Two practitioners on Kearny Street spend each one thousand dollars a month, and one on Market, two thousand. This last declares that his receipts from his practice and sales of nostrums will average *one hundred dollars a day*. The amount (average) filched from their dupes by each of these swindlers cannot be less than two hundred dollars a month, or one hundred thousand dollars in the aggregate. This is $1,200,000 a year.

[1] At the generally accepted rate of two epileptics per thousand inhabitants.

ERYSIPELAS OF THE UPPER AIR-PASSAGES, WITH CASE.

By D. BRYSON DELAVAN, M.D.,
NEW YORK.

Since the remarkable and exhaustive thesis of Cornil, which appeared in the *Archives Générales de Médecine*, in 1862, little new information has been advanced upon the subject of erysipelas of the upper air-passages. An excellent *résumé* of it has been given by Morell Mackenzie in his book upon diseases of the nose and throat. In this he states that he has seen but four cases.

Pathologically erysipelas of the upper air-passages is similar to the same malady when situated upon the external surface of the body. It may occur either primarily, or by extension from the face along the mucous tracts of the mouth, nose, or ear. Its causes are the same as those which give rise to it when situated upon the surface, although it has been observed most often in the course of general epidemics of the disease. Of eighteen cases recorded, in which the pharynx was affected, fifteen were under the age of thirty, and two-thirds were females.

Cornil makes three divisions of the malady, viz.: (1) Erysipelas with simple redness; (2) erysipelas with phlyctenulæ; (3) erysipelas terminating in gangrene. The disease most commonly reaches the larynx from the pharynx, and it may extend still farther down the respiratory tract and involve the trachea and bronchi.

As to the prognosis, the dictum of Hippocrates, namely, "When erysipelas extends from within outward, it is a favorable symptom, but when it removes to the internal surfaces, it is a deadly one," has been confirmed by modern observation. In nine cases analyzed by Cornil, when the face was first attacked, seven deaths occurred; whereas in nine other instances, in which the enanthem preceded the skin eruption, seven recoveries took place.

From what has been already said it will appear that the disease under consideration is rare. In this country cases have been reported by Drs. De Blois, of Boston; Porter, of St. Louis, and Roe, of Rochester, as well as by the writer, who, at the meeting of the American Laryngological Association, held June 24, 1885, read an article upon this subject, in which the records of two original cases were given.[1]

From the fact that erysipelas of the throat is probably more common than would be supposed from the small number of cases recorded, and because of the serious dangers which it may occasion, it has seemed well to call attention to the following case, the symptoms of which were exceedingly well marked and severe, and in which, although extension of the inflammation from without inward took place, recovery resulted.

G. T——, Scotland, aged forty-seven, stonecutter, married. Family history and previous record good. Fourteen years ago had an attack of facial erysipelas. Present attack began upon February 3, 1887. The inflammation appeared first upon the cheeks but quickly extended to the external surface of the nose, which became enormously swollen. Thence in the next four days it made its way over the forehead, scalp, and ears. Meanwhile the general symptoms were severe; pyrexia, anorexia, prostration, constipation. About February 16th the attack upon the surface of the head having begun to abate, the patient was attacked with pain in the pharynx and dysphagia, whereupon the inflammation extended to the nasal cavities, the upper pharynx, the faucial region, the larynx, the mouth, and the adjacent glands. This was attended with a return of the general symptoms in greater severity than before. There was also mild delirium and decided mental hebetude.

February 26th.—An abscess of the pharynx was incised and about one ounce and a half of dark bloody serum evacuated. The patient reported at the Demilt Dispensary, and was then seen by the writer.

[1] New York Medical Journal, September 12, 1885.

February 28th.—At this time the disease was at its height; the general condition was one of great prostration. There was the appearance over the face and scalp of a recently resolved attack of erysipelas. Great emaciation; mental condition dull; pulse feeble. Examination of the upper air-passages showed intense congestion of the nasal, pharyngeal, faucial, and laryngeal regions, which were filled with an abundant muco-purulent secretion. There was tumefaction at both sides of the pharynx behind the tonsils, particularly well marked on the right, where, he stated, the abscess had existed, pronounced œdema of the epiglottis, the arytenoids, and the ary-epiglottic folds, slight dyspnœa, and intense dysphagia.

Had been taking little nourishment and no medicine except quinine for several days.

Treatment.—The nose and pharynx were sprayed with an alkaline and antiseptic solution and all secretion removed. Especial care was taken to cleanse the nasal passages and pharynx by means of the anterior nasal spray. The result was immediate and marked relief. The early acute stage having passed and no advantage being likely to accrue from the use of ice, there were ordered inhalations of benzoated steam, once every half hour; a spray of a solution of chloride of zinc, three grains to the ounce, every hour; tincture of the chloride of iron, fifteen drops every two hours; sulphate of quinine, two grains every six hours; and abundant nourishment in the shape of milk, beef-tea, oatmeal-gruel, raw oysters, and raw eggs.

March 2d.—Patient's condition had greatly improved. Was able to swallow easily, and was almost free from pain. Local condition better; mental dulness less apparent; treatment continued.

March 4th.—Still improving. General condition infinitely better. Local treatment decreased in frequency of application.

March 7th.—Local condition excellent; gaining rapidly in flesh and strength. Mind clear and vigorous.

Complete recovery in about ten days, during which time the case presented nothing worthy of record.

1 East Thirty-Third Street.

Clinical Department.

LOCAL TREATMENT OF DIPHTHERIA BY THE BICHLORIDE OF MERCURY.

Dr. E. L. Oatman, of Nyack, writes that for the past two years he has treated diphtheria by the local use of a solution of the mercuric bichloride, and has been greatly pleased with the results obtained. "Iron in large doses and free stimulation certainly play an important part in the treatment; but with these alone I lost—at St. Agatha's Asylum—ten out of twenty-three cases, while since the addition of local treatment by the mercuric solution, I have lost but one out of thirty-four subsequent cases. This patient died two weeks after the subsidence of all the local symptoms, from paralysis of the muscles of respiration. Seven of my cases have had more or less paralysis of the muscles of deglutition during convalesence. This appears to be a large percentage and might direct some suspicion toward the mercury as being in a measure causative. The details of treatment in an ordinary case, and as followed in the hospital ward, is as follows: I manufacture on the spot about fifty swabs—made by twisting absorbent cotton around a stick about the size of a lead-pencil. The cotton should be pulled our and twisted firmly around the tip of the stick, extending beyond it, that the end may be thoroughly protected, so that no injury be done while using it. This is dipped in a solution of the bichloride of mercury, two grains to one pint of water, and is passed into the throat until it touches the posterior wall of the pharynx. It is then instantly withdrawn and burnt. No swab should ever be used a second time. No attempts are made to rub off any of the membrane, but more or less always adheres to the swab. This procedure is repeated hourly, day and night, until the disease begins to subside—which it usually does in forty-eight hours. I follow every application by the internal administration of five to ten minims of tincture of the chloride of iron, and as much whiskey and milk as the case appears to demand. If the interior or posterior nares are invaded, the nose should be syringed. The conical urethral syringe is the safest instrument to leave in the hands of a non-professional nurse. It is of the first importance that the nurse or mother be fully instructed in the method of treatment, and should make the application satisfactorily to the physician before being left in charge of the patient. In no case have I ever experienced any difficulty in getting my instructions carried out, or met with any serious resistance from the patient. Spraying the throat is a far more difficult procedure for the lay attendant, as the tongue obstructs the passage, while none of the loose membrane and mucus is removed as with the swab, but is swallowed and systemic infection furthered. The diphtheritic membrane cannot flourish in contact with the bichloride of mercury, and if this invaluable agent be constantly applied to the diseased surface for a few hours, the poison will be destroyed. I attach great importance to the method of application, and the extraction of the loosened membrane, beneath which the poison is still active, but inaccessible to the antiseptic.

HOW SHOULD SANTONIN BE PRESCRIBED TO OBTAIN ITS FULL PHYSIOLOGICAL EFFECT?

Dr. K. A. Norderling, of Rockford, Ill., communicates the following: "After the introduction of santonin into the system, the urine will in a short time become of a cherry-red color. Santonin will give the same color when dissolved in an alkaline solution, or when heated to liquefaction with the addition of caustic potash. The drug, therefore, undergoes in the system a change similar to that produced by alkalies and heat. Santonin is insoluble in water and dilute acids, but dissolves in the saliva, the gastric, intestinal, and pancreatic juices. This solution in the gastric juice takes place so rapidly that the maximum dose is completely absorbed in the stomach, as has been shown experimentally by Lewin. But it has also been proved by experiment that santonin, when given in an oily solution, is not at all absorbed in the stomach, but the entire quantity passes into the intestine. It is evident that when the drug is given in powder it will be absorbed and taken up in the circulation before reaching the intestine, and consequently, in order to obtain its vermicidal effect, it must be administered in such a form that it will not be acted upon by the gastric juice. Küchenmeister has shown that the drug must be in solution, as he found that ascarides were not affected by santonin-crystals floating in water, but were killed when brought in contact with an oily solution of the drug. In order, therefore, to accomplish its therapeutic object, it is necessary that santonin be in a form in which its vermicidal action can be exerted, and also that it reach the habitat of the parasite. To make the solution, any form of oil may be used, and the best effect is obtained by three grains of santonin dissolved in two ounces of oil, to be taken in four doses. It is also a good practice to add one drop of wormseed-oil to each dose, as researches have shown that all ethereal oils are poisonous to the lower organisms. If a movement of the bowels is desired, castor-oil will be suitable, although not in too large a dose, because with strong peristalsis the santonin does not remain long enough in the intestine to produce the desired effect. About two drachms of the oil to each dose will be sufficient."

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, April 23, 1887.

A NEW METHOD OF INTRAPULMONARY INJECTION IN THE TREATMENT OF PHTHISIS.

IT is very interesting to note the efforts that are being made in all parts of the world to discover some mode of treatment for pulmonary phthisis by which the disease may be controlled. They are all, of course, based upon the new views of the etiology of the affection which have gained credence in recent times since the discovery by Koch of the tubercle bacillus. Of these different methods we propose to speak more at length at some future time, but now we will refer only to the latest one of which mention has been made in the current literature.

In a communication made to the Medico-Chirurgical Society of Pavia (*Gazzetta degli Ospitali*, March 23, 1887), Professor A. Riva gave an account of some experiments made by him with a modified form of intrapulmonary injections. He was not satisfied with injecting a few drops of some substance inimical to the bacilli, but endeavored to saturate the entire pulmonary tissue in the neighborhood of the diseased part. He argued that these injections were spread throughout the pulmonary tissue, and that, consequently, they reached the parts at the periphery of the diseased portion in such a dilute form as to be practically inert. It was necessary, therefore, to inundate the parenchyma of the lung so thoroughly with the fluid as to destroy all the bacilli present. That this was not done by the ordinary method was the explanation, he thought, of the want of uniformity in the results obtained.

The injections were made by means of a simple apparatus consisting of a graduated glass tube, of a capacity of 30 c.c. (1 ounce), to the lower end of which was attached a piece of flexible tubing of suitable length. To the other extremity of the tubing was fastened a large-sized hypodermatic needle, 10 c.m. (4 inches) in length. Before the injections were made the whole apparatus was thoroughly sterilized, and the needle, when not in use, was kept in a test-tube filled with a solution of carbolic acid. For the injections a solution of bichloride of mercury, of a strength of from 1–3,000 to 1–5,000 was employed.

The needle was passed from the anterior surface of the chest, at a point corresponding to the seat of the lesion, directly back to the posterior portion of the lung, care being taken not to exceed this limit and enter the pleural cavity. If the point of the needle should happen to lie within the lumen of a bronchiole, the entrance of fluid would excite violent cough, and for this reason the author was accustomed to allow but two or three drops to enter at first, and then, if there was no cough, a larger quantity could be safely injected. As the injection proceeded, the needle was gradually withdrawn so as to bathe the entire portion of pulmonary parenchyma lying in its course. If thought advisable, the needle could be moved about from side to side so as to spread the fluid over a greater area. But this was not ordinarily necessary, as diffusion occurred so readily that the entire apex would be bathed in the solution although it was injected only along a single line. Although as much as 40 to 50 c.c. of a 1–3,000 was injected at one time, and 75 c.c. of a 1–5,000 at another, the author never saw any symptoms of mercurial poisoning. Only once, after a number of injections had been made, was a slight swelling of the gums noticed. It would seem, therefore, that no danger of poisoning is to be apprehended. The danger of wounding a blood-vessel would, however, appear to be more real. But there are few vessels of any considerable size at the apex of the lung, and Dr. Riva, in upward of a hundred injections, never saw any signs which led him to suspect that such an accident had occurred. The injections were made very slowly, the operation usually lasting about an hour, and were repeated every three or four days.

The results obtained were not very brilliant, it must be admitted, although they were sufficiently encouraging to warrant a continuance of the experiments. The number of bacilli in the sputa were notably diminished, though in no case did they entirely disappear. The operation was well borne, and the patients complained of no discomfort during its continuance.

Dr. Riva is still experimenting with these large injections, and promises to communicate the results obtained in another paper. Judging, however, from the results in this first series, the method seems to offer no advantages over the ordinary form of pulmonary injections.

THE TREATMENT OF THE URIC-ACID DIATHESIS.

IN a recent series of articles on the treatment of gout and the uric-acid diathesis, Dr. Mortimer Granville (*Medical Press and Circular*) advances some views radically different from those ordinarily taught.

Dr. Granville appears to regard the presence of an excess of uric acid in the blood as the essential condition in this trouble. The local disturbances are due, he thinks, to accumulations of the acid in various localities —all of which is sufficiently in accord with prevalent views. But while admitting the excess of this acid in the blood, he does not admit the great acidity of the urine, or that the urine contains less than the normal amount of urea, or a deficiency or excess of uric acid, according to the stage of the attack. He has tabulated the results of several hundred determinations made in cases of gout in its regular and irregular forms. The figures adduced, showing specific gravity, acidity, and the proportional quantities of urea and uric acid in several groups of urines examined, do not appear to present any specially abnormal features, and thus bear out the negative opinion

stated, although the author is careful to point out that it is premature to express a decided judgment.

In treatment, he does not give the so-called specifics, or alkaline carbonates, but advocates a medicine which, he claims, breaks up the uric-acid compounds. This drug is iodine, and it is believed to set free the acid from its bases. Large amounts of water are then to be drunk, for the purpose of "flushing" the kidneys and washing out the morbific matter.

Dr. Granville is an attractive writer and a "happy therapeutist," but we are inclined to share the criticism made upon his article by a contributor to the *Press*, who writes:

"On reading the articles which have appeared in your valuable journal during the last few weeks, one 'On Gout,' by Dr. Mortimer Granville, and the other touching on the same subject in 'The Neurotic,' by Dr. Milner Fothergill, one cannot help being struck by the very crude, undigested notions both gentlemen possess as to the formation of uric acid in the system. In dealing with gout and its cause, no writer on the subject can afford to be ignorant of the experimental researches of Professor Ebstein, of Göttingen, a translation of whose work on the subject ('Die Natur und Behandlung der Gicht') appeared in your pages, and which has, I understand, since appeared in book form. The value placed on Ebstein's researches is further shown by the fact that the volume has since been translated into the French language. To talk about the liver being the workshop in which uric acid is formed, after the appearance of Professor Ebstein's work, is a display lamentable enough to cover an Englishman with shame and confusion of face. Might one be indulged in the question, 'Are our therapeutics only abreast with our pathology?'"

Ebstein's theory, which is not universally accepted by any means, is that uric acid is manufactured by cartilaginous and connective-tissue metabolism, not by the liver.

UNIVERSITY COURSES AND MEDICAL EDUCATION.

The average age of students who enter Harvard has been gradually increasing, until now it is nearly nineteen years. The alumnus of twenty-three who takes a medical and hospital course is nearly twenty-eight years of age before he begins to practise medicine. This is too old, and it is evident that such a course is not to be recommended. The average age at which German medical students begin professional studies is eighteen and four-tenths, and they begin practice when twenty-three and a half. English physicians begin when about twenty-four, and French when at about the same age.

In view of the above facts, says the *Boston Medical and Surgical Journal*, the Medical Faculty of Harvard University have recommended to the consideration of the Academic Council—a body representing the undergraduate department as well as the various schools—the expediency of granting the degree of A.B. to all undergraduates who shall subsequently take the longest course of study offered at the professional schools after three years' attendance (at the end of the junior year) in the Academic Department; the professional degree and that of A.B. to be given simultaneously at the end of the professional course, it being understood that the requirements of each have been fulfilled. The first year of a professional school would thus be made equivalent to the present senior year.

Dr. H. P. Bowditch, Dean of the School, proposes a still more radical change, viz.: (1) An academic course of three years, with requirements so graded as to lead to the degree of A.B. at an average age of twenty years; (2) a philosophic course of three years, with requirements so graded as to lead to the degree of A.M. or Ph.B. at an average age of twenty-three years.

In other words, Harvard is to go back to the courses or standards of twenty-five years ago for its A.B. degree.

Whether this is practicable or not, it is very certain that no large number of persons intending to study medicine will set out for themselves a course of study which does not equip them for work until they are twenty-seven or twenty-eight years of age.

Yet academic training is an invaluable help in medical work, and ought to be had whenever practicable. Students will, therefore, if wise, either go to smaller colleges, which let them out at twenty or twenty-one years of age, or the larger colleges must adopt some such plan as Dr. Bowditch proposes. Colleges or universities in which the freshmen are fully nineteen years of age are failures, as educators of medical men at least, and we believe it is much the same with lawyers.

THE DECLINE OF AMERICAN MEDICINE.

Our young contemporary, the *Medical Standard*, writes in a very Stygian mood as regards the present condition of American medicine.

The fee-bills, it says, of most medical societies of the second decade of the present century are practically identical with those of the medical societies of the present time. American medical remuneration is now much less, proportionately, than it ever has been. With this decrease in pecuniary reward has come an almost equal decrease in social recognition. The physician no longer towers above the community as a member of that famous aristocratic triumvirate of the first three decades of the present century—the "parson," the "squire," and the "doctor." The "squire" has risen in prominence, but the "doctor" has fallen. Furthermore, we are told that there are no such towering giants as in the old days of Rush, and Mott, and McDowell. The scientific status of American medicine is also lower; and, in fine, we are all going to the bad. The explanation of all this is stated with a candor and precision characteristic of a great commercial centre instinct with true business feeling. It is because we as a profession have indulged too much in "humanitarian cant" and "canting pseudo-philanthropy," and have not kept pace with the business feeling and business methods of the age. The remedy, if we understand our contemporary correctly, is to give up philanthropy or, rather, pseudo-philanthropy, and conduct all professional affairs on business principles, or, to be more euphemistic, be guided by the principles of an advanced political economy.

The *Medical Standard* is no doubt right, in large measure, as regards the decline in compensation for medical services. In many parts of the country this is relatively lower than formerly; and in this city we know of

many of the older physicians who have been forced to lower their rates because these have been cut into by younger men, with no pseudo-philanthropy about them, but thoroughly penetrated with the principles of political economy as taught by advanced business men of the day. However, it has to be confessed, also, that a considerable part of medical work in the line of practice is done in a cheap way, by men who are really not trained to careful medical examinations and thoroughly rational methods of diagnosis and therapeutics. The country is full of cheap doctors, and the alertness of Americans is such that they appreciate the fact that most of their routine and empirical dosing is not worth a high price. We believe, however, that the best medical talent still commands as high returns as ever, while in many special lines of work the compensation is greater than formerly. There are also many more examples of first-class talent now than existed sixty years ago. We have many better surgeons, and more brilliant and accomplished men, than Valentine Mott, or Ephraim McDowell, or Payne, ever was. The day of oracles in medicine and surgery, to be sure, is past, and no one man will ever gain such supremacy as was done in the days gone by. But this is because times have changed, and the relations of physicians to each other and to the public are entirely different, Knowledge and the critical spirit are more widely diffused. American medicine is not on the wane; and it will, we trust, never entirely abandon humanitarian sentiments for business methods. Its hope lies in the continual improvement in the training of students and physicians, until the public learns that there is a difference between doctors, of a very decided kind; that good medical service is worth liberal compensation and pays best in the end.

DESCRIPTIVE SCIENCE.

A GREAT deal of what is contributed by medical men to current literature is simply of a descriptive character, and has value mainly because it is interesting to, and refreshes the memory of, those engaged in the same fields of work. How far even the records of accurate observation are from deserving a place with true science is illustrated by an anecdote told of Agassiz, when he was still a young man, and had but recently arrived in this country. At a meeting of a distinguished literary and scientific club of Boston there was a discussion of Dr. Hitchcock's then new book on "Bird Tracks," and the plates representing his geological discoveries were exhibited. The praises had been lavish, when a young foreigner, a stranger to most of them, arose and said: "The defect in this book is that it is dees-creep-teeve, and not com-par-a-teeve." With that sentence came the distinction in American science between scientific observation and scientific intelligence, between the art of perceiving and describing and the art of comparing and combining.

Few have this greater art, and most must be content with modestly and faithfully recording what is found new in the world of pathology. But even to be able to observe and describe accurately is no small talent, and so reports of cases, if reported well, must always have a value.

Since, however, most of our medical science is necessarily "dees-creep-teeve," additional pains must be taken that the descriptions show accuracy in every point, and that they contain no second-hand stories of familiar things.

BOB-VEAL AS A FOOD.

THE inspectors of the City Health Department recently seized several thousands of pounds of bob-veal. It is said that for every pound of this form of food captured five pounds are sold and consumed in the city.

The inquiry is sometimes made why bob-veal is treated with so little consideration by our health-officers. It is perfectly true that bob-veal is neither poisonous nor innutritious. The only objections are that it is a watery and rather indigestible substance, standing somewhat in the relation to good veal or beef that skimmed milk does to the pure article. Veal, as would be expected, has almost identically the same amounts of fat, nitrogenous matter, and salts, as beef. The tissues, however, have less osmazome, or flavoring matter, are more insipid, and hard to digest.

It is a question, however, whether even the bobbest of bob-veal is not better food than the "lights" which are sold to and eaten by the poor. Bob-veal ought not to be sold for good veal; but under its own name, and at a low price, it might be admitted as an article of food.

A FURTHER STUDY OF FEVER.

Two series of lectures have recently been delivered upon the nature of fever, and in both we find scholarly and ingenious contributions to the subject. The Croonian Lectures, by Dr. Macalister, furnish the more elaborate discussion, and his views will attract, deservedly, much attention; for they present to the reader a decidedly new terminology and, in some respects, new conceptions, and place the pathology of fever in closer accord with modern physiological doctrines.

The temperature of our body is due to the action of a heat-generating mechanism, the great source of the heat being the metabolic changes in the muscles. The loss of heat is controlled by a heat-losing mechanism, mainly associated with vaso-motor and respiratory activity. The balance between heat-production and heat-loss is maintained by a heat-adjusting apparatus. These various processes are termed by Macalister thermogenesis, thermolysis, and thermotaxy. The three mechanisms are successively evolved as we ascend in the animal scale. Cold-blooded animals have little more than a thermolytic or heat-losing mechanism. Infants have only the thermogenetic and thermolytic, there being hardly any adjusting mechanism, as is shown by the instability of their temperature. Fever is a dissolution-process—the last mechanism evolved, the thermotaxic, gives way first, then the thermogenetic, and lastly the thermolytic. Conversely, when the patient convalesces thermolysis is first restored to normal, then thermogenesis, then thermotaxy.

The anatomical basis of these various mechanisms is as yet only partially made out. Wood claims to have shown that there is a thermogenetic centre, inhibitory in character, near the crucial sulcus in the dog, while Arohn-

son and Sachs find a heat-generating centre near the inner side of the corpus striatum. Stimulation of this region increases the temperature on the opposite side. Those nerve-centres whose influence promotes metabolic change are known as catabolic, and they correspond to the motor centres for muscle; those centres which inhibit metabolism are "anabolic," or inhibitory. There is good reason to believe that the thermogenetic mechanism has anabolic (centre of Wood's) and catabolic (centre of Arohnson and Sachs) centres. The thermic fibres below the medulla mingle with vaso-motor nerves so that they cannot be further followed.

The thermolytic mechanism is one which is intimately connected with vaso-dilator, vaso-constrictor, secretory, and respiratory functions. The vaso-motor system is, however, the great agency through which heat-loss is regulated.

A point of the greatest practical interest in connection with the modern study of fever is brought out again by Macalister. It is that, since fever depends upon a disturbance in the relations between heat-production and heat-loss, the condition revealed by the clinical thermometer may be very misleading. The patient, for example, with a temperature of 104°, may simply suffer from insufficient heat-loss, with perhaps a trifling increase in heat-production.

Practically, however, experimentation shows that heat-loss and heat-production work together quite closely, and that in fever, while both are affected, the increase affects the production a little more than the loss; hence the rise of temperature.

News of the Week.

A New Medical Journal is to be published shortly in Paris, under Professor Grancher's direction. It will be called the *Univers Médical*, and the editor intends to devote a much larger part to foreign news than is usually given in French papers.

Consumption is quite prevalent in Dakota, according to Dr. J. E. Engstadt, in the *Medical Age*. The Indians especially suffer from it, and so do the Norwegian immigrants.

How Dr. Murrell Prevented a Suicide.—In the preface to the last edition of an English medical work entitled "What to Do in Cases of Poisoning" the author, Dr. Murrell, says: "This work has reached a fifth edition, but it is not my fault, and I disclaim all responsibility in the matter. I am told that it has been the means of saving many lives, and I have no doubt this is true, for I hear that a gentleman who thought of poisoning himself changed his mind on reading the directions for treatment."

Dr. Holmes and the Druggists.—At a banquet given to Mr. Theodore Metcalf, by the Boston Druggists' Association, Oliver Wendell Holmes gave his opinion of apothecaries as follows: "I have always had a great opinion of the medical advice of apothecaries. The truth is, they put up the prescriptions of all the best physicians in the place in which they live, and they have the very cream of all their wisdom at their fingers' ends. So, when I have myself been suffering from any slight bodily inconvenience, I am ashamed to say—or ought to be, perhaps—instead of going to a professional brother, I have quietly crept into the back room and asked Mr. Metcalf what such and such a doctor was in the habit of prescribing.—"*Boston Medical and Surgical Journal.*

A Jubilee Hospital at Montreal.—A telegram from Montreal states that Sir Donald Smith, Member of Parliament, and Sir George Stephen, President of the Canadian Pacific Railway, have offered to give $500,000 each for a new hospital, to be named the Royal Victoria Hospital. The city is asked to give a site on Mount Royal, adjoining the estate of the late Sir Hugh Allan. The building is to cost about $250,000, which would leave an endowment of $750,000. This, it is estimated, would bring in about half the necessary revenue for the maintenance of the two hundred patients for whom accommodation is to be provided.

The West and the International Congress.—The President of the Congress is a Western man. The home of the Secretary-General is in the West, and the sections are largely made up of Western men, many of whom have received their degrees from Western colleges.—*Weekly Medical Review.* Yet when the preponderance was of Eastern men great indignation was expressed.

Hospital Mismanagement in Chicago.—The warden and others of the officials of Cook County Hospital have been indicted for fraud by the Grand Jury, and, with several of the County Commissioners, with whom they were in connivance, will shortly be tried for fraud and malfeasance. The abuses which they have perpetrated are said to be flagrant and of long standing.

Transplantation of Human Bone in a Case of Ununited Fracture.—Professor A. Poncet, of Lyons, reports the case of a man of forty-three years who suffered from an ununited fracture of the tibia, the ends of the bones being atrophied and 35 mm. to 40 mm. apart. He removed the first phalanx of the great toe, on a limb recently amputated, sawed off the articular ends, and split the bone in two. One of these halves, 26 mm. long, was fastened between the freshened ends of the broken tibia, with due antiseptic precautions. Fibrous union took place at one end, osseous at the other. There was no necrosis.

American Public Health Association.—The fifteenth annual meeting of this Association will be held at Memphis, Tenn., on November 8 to 11, 1887. The subjects for discussion will be the following: 1, The Pollution of Water Supplies; 2, The Disposal of Refuse Matter of Cities; 3, The Disposal of Refuse Matter of Villages, Summer Resorts, and Isolated Tenements; 4, Animal Diseases Dangerous to Man. Dr. G. B. Thornton, of Memphis, will give all information concerning the local arrangements.

The Bill for Drinks.—The sum of $700,000,000 is spent annually for alcohol by the 15,000,000 drinkers of this country, and the sum of $600,000,000 by the 8,000,000 drinkers of Great Britain and Ireland. So the mother country is still ahead.

A Suit against the Health-officer of this Port and a rag-disinfecting firm has been brought by certain rag importers of this city. It is claimed that the rags were unlawfully detained in order to be put through an unnecessary patented disinfection process.

The Microbe of Typhoid Fever.—At a recent meeting of the Société des Hôpitaux, M. Chantemesse made an interesting communication concerning the morphological and biological characteristics of the typhoid-microbe. The sporulation of this microbe takes place between 19° and 48° C. (67° to 104.4° F.). It develops in water, even if sterilised. At a temperature of 45° C. (113° F.) the cultivations live for several days; they are destroyed by boiling. This microbe retains its vitality in damp ground. Corrosive sublimate (1 in 20,000) and sulphate of quinine (1 in 800) destroy it. Carbolic acid (1 in 400) has no effect on it; hydrochloric acid is also inert, therefore the acidity of the stomach is not inimical to this microbe.

Biniodide of Mercury as an Antiseptic.—Dr. P. K. Bolshesolsky, of St. Petersburg (*Vratch*, No. 11, 1887, p. 220), from numerous experiments made by himself in Professor A. P. Dobroslavin's laboratory, concludes that biniodide of mercury is a more powerful and less poisonous antiseptic than corrosive sublimate. Thus he fully confirms the observations of Bernhardy. A solution of 1 in 4,000 destroys putrefaction-microbes more completely than a sublimate solution of 1 in 2,000. The biniodide dissolved in a solution of iodide of potassium was recently tried, with apparently good results, in three cases of laparotomy, under Professor A. I. Krassowski. For washing the floor, a solution of 1 in 4,000 was employed; for disinfecting the hands, 1 in 2,000; for instruments, 1 in 2,000 and 3,000.

The Alleged Assault.—We take pleasure in stating that the practitioner who gave the certificate of assault referred to in our last issue is a German physician in good and regular standing, and that in giving his testimony he was guilty only of an error of judgment. We are glad to learn that the certificate was written under protest, with no desire to criminate a brother practitioner, and that it was used by the attorneys in the case in a different manner from that intended by the writer. The great mistake was in giving any certificate which should even indirectly reflect upon the moral character of a brother practitioner.

The Proposed Diphtheria Hospital in this City.—The necessity for a hospital specially devoted to patients suffering from diphtheria has been urged by the profession from time to time, but until lately no practical turn has been made in the proper direction. The *Morning Journal*, of this city, with commendable far-sightedness and logical force, has initiated a movement which promises as equally gratifying a result as has crowned its labors in the cause of tenement-house reform. It can be assured that in both it has the support of the profession. An appeal has been made to the public for funds, and there is no doubt that subscriptions from the more substantial of our citizens will be forthcoming. We have no doubt that such an institution, suitably constructed and properly managed, will not only tend, by isolating the patients, to check the spread of an alarmingly prevalent and fatal scourge among the poor, but will offer better opportunities for the treatment of the disease, and, by the enlarged experience of its medical staff tend still more largely to develop their therapeutical resources. The medical staff will be composed of gentlemen who have had ample opportunities for studying the disease in all its phases, and will command the confidence and support of the profession. It is proposed to construct a model hospital-building in a suitable locality, to admit thereto cases of diphtheria from the tenement-house districts, and, by means of a heated crib, to obviate any change of temperature during the transfer. The urgency for the establishment of such an institution is quite apparent in the fact that no general hospital will admit such cases, and that there is at present no building which has been specially set apart for diphtheritic patients.

A Critic Criticised.—Dr. F. M. Meyer writes to *Gaillard's Medical Journal* criticising the prevalent practice of writing the A.M. degree first after the name and then the M.D. As the M.D. degree is generally obtained first, it should, he thinks, be placed first. Dr. Meyer signs his name "J. M. Meyer, A.B., M.D., A.M." We would ask, however, how a person can be a Bachelor of Arts and a Master at the same time. It is much like a man being engaged and married cotemporaneously. Such things occur, but are generally thought bad form.

A Prize of Two Thousand Dollars (10,000 francs) is offered by the Académie de Médecine, Paris, for the best work on the treatment of stricture of the urethra or on the therapeutic methods for diseases of the urethra.

Dr. Edward T. Caswell died in Providence, R. I., on April 17th, in his fifty-fourth year. He was a son of the Rev. Alexis Caswell, at one time President of Brown University. He was graduated from Jefferson Medical College in 1857, studied a few years in Europe, and then settled in Providence.

Obituary.

JAMES STEWART JEWELL, M.D.,

CHICAGO, ILL.

We regret to announce the death of Dr. J. S. Jewell, of Chicago, Ill., which occurred on April 18th. Dr. Jewell had been in poor health for a considerable time, and although not so ill as to be compelled to relinquish his practice entirely, his condition was such as to cause grave apprehensions among his friends. He began to break down in health about five years ago, and a complication of disorders set in which he was never able to overcome. Dr. Jewell was born, September 8, 1837, at Galena, Ill. He was graduated at the Chicago Medical College in 1860, and two years later he settled in Chicago, where he remained in active practice till the time of his death. From 1864 to 1869 he was Professor of Anatomy in his college, and since 1872 had held the chair of Nervous and Mental Diseases. In 1874 he started a *Journal of Nervous and Mental Diseases*, which still exists as a prosperous periodical and has done much to promote neurological study in this country. Dr. Jewell was also instrumental in organizing and making successful the American Neurological Association. Dr. Jewell was of a studious and philosophic mind, yet he was a skilful physician, ingenious and practical in his methods. His services to American neurology are very great.

Reviews and Notices of Books.

A Reference Handbook of the Medical Sciences, embracing the Entire Range of Scientific and Practical Medicine and Allied Sciences. By various writers. Illustrated by chromo-lithographs and fine wood engravings. Edited by Albert H. Buck, M.D., New York City. Vol. IV. New York: William Wood & Co. 1887.

This volume of the "Reference Handbook" carries the work along from ICH to MIL. Some very important articles are embraced in these letters, such as Insanity, Kidney, Labor, Larynx, including a notice of O'Dwyer's method of intubation, Liver, Lungs, Micro-organisms, and Microscopy. These are only a few of the more important subjects which are treated at considerable length, but there are hundreds of other minor topics which are, in their way, of nearly equal importance, and which are discussed in a thoroughly practical and lucid manner. We mentioned, in a notice of a previous volume, a comparative table of the Centigrade and Fahrenheit thermometric scales, and we find here another very convenient table of the metric and British systems of linear measurements. Such tables are exceedingly useful, and even a necessity in the present period of transition, when all the Continental writers, and many also in England and America, use the decimal system; but the convenience of readers of the Handbook would be greatly promoted were the tables printed on loose sheets, for ready reference, as it is awkward, while reading an article in one volume to be obliged to turn to another to find a translation of the figures employed. The book before us contains, in addition to over five hundred wood-cuts, three chromo-lithographic plates illustrating Carcinoma and Sarcoma of the Larynx, and the different appearances presented by test-tube cultures of a number of the more important micro-organisms. The contributors to this volume are ninety-five in number. Among the more important articles may be mentioned those on "Inflammation," by Dr. W. T. Councilman; on "Insanity," by various authors. Some of the illustrations of this section of the volume are of great interest. Dr. Joseph D. Bryant has contributed a valuable article on the "Intestines." The articles on "Kidney," "Labor," "Larynx," "Liver," "Lungs," "Massage," "Micro-organisms," and "Microscopy" are remarkably complete. Aside from these, the great number of short, succinct descriptions and statements with which this volume is crowded give the work its chief value to the profession. We need only add that the high reputation which the work has already earned for itself is fully sustained in the present volume.

Alpine Winter in its Medical Aspects: With Notes on Davos Platz, Wiesen, St. Moritz, and the Maloja. By A. Tucker Wise, M.D., L.R.C.P., M.R.C.S., formerly Visiting Physician to the Infirmary for Consumption, Margaret Street, Cavendish Square; Physician to the Western General Dispensary, etc.; Author of "Davos Platz, and the Effects of High Altitude on Phthisis;" "Wiesen as a Health Resort in Early Phthisis," etc. Third Edition. London: J. & A. Churchill. 1886.

The appearance of the third edition of this well-known and highly appreciated treatise on the Alpine winter resorts will be welcomed by all who are interested, and what physician is not, in satisfying himself as to the relative merits of warm and cold climates in the treatment of pulmonary phthisis. The author justly insists upon the necessity of greater attention being paid to house ventilation in mountain winter resorts, where, of necessity, much time must be passed in-doors, and where the climate does not admit of ventilation through open windows. And especially interesting is his description of the Maloja Kursaal, in the construction of which the primary object has been to secure proper ventilation and heating, which would seem to have been effectually obtained. Dr. Wise is, of course, an advocate of high altitudes in a cold climate for the winter treatment of phthisis, yet he has presented his case fairly, and seems not to be blind to certain drawbacks which the Alpine resorts possess. The book will be found entertaining and instructive to all those interested in the climatic treatment of disease.

The Extra Pharmacopœia of Unofficial Drugs and Chemical and Pharmaceutical Preparations. By William Martindale, F.C.S., Late Examiner of the Pharmaceutical Society, and Late Teacher of Pharmacy and Demonstrator of Materia Medica at University College. With References to their Use abstracted from the Medical Journals, and a Therapeutic Index of Diseases and Symptoms. By W. Wynn Westcott, M.B. Lond., Deputy Coroner for Central Middlesex. Third Edition. London: H. K. Lewis. 1884.

The title fully explains the nature of this little book, which cannot fail to be of use, especially to those who have failed to keep thoroughly posted on the new remedies, and new applications of old remedies, concerning which so much is constantly appearing in the periodical literature of the day.

Transactions of the Academy of Medicine in Ireland. Vol. IV. 1886.

The present volume brings together a number of papers of varied and varying interest. Dr. J. M. Purser, in a paper on "The Therapeutic Uses of the Digestive Ferments," deprecates their use within the body, and any good results which would seem to accrue from the administration of pepsin, trypsin, or other ferments are due, not to the supposed chemical action which they exert in vital processes, but to suggestion. They are merely placebos; but ferments are of use to perform artificial digestion, and the administration of digested material is both scientific and attended by the best results. Such a paper as this is both timely and suggestive.

Dr. James Martin endeavors to prove the non-infectious nature of pneumonia from twenty-eight cases, no two cases, except in one instance, having occurred in the same family, though each patient was nursed in his poor and too often impure home by wives, mothers, sisters, and brothers, all in the closest contact. In the majority of cases the patient described his illness as originating with some especial exposure to cold air or wet clothes; the weather, too, was severely cold with a prevalence of sharp winds.

Dr. N. Langford Symes reports an extraordinary case of hyperpyrexia (temperature 108°) in rheumatic fever, and great success resulting from packing the patient in cloths wrung out of ice-water.

Mr. R. F. Tobin has an interesting paper on "The Surgery of the late Expedition to Suakim." In 129 cases, 93 were wounded by rifle-shots and 36 by sword or spear; 124 recovered—a very remarkable record when taking into consideration "the nature of the climate, the difficulty of conveyance by land and sea, the septic conditions implied by flies that made black by their presence every spot where they could obtain food."

Dr. Thomas Madden More discusses and describes Dr. Emmet's "buttonhole" urethral operation for chronic cystitis. One obtains an idea of laparotomy as it at present exists in Ireland from a paper by the same gentleman, and Dr. Atthill has a paper on "Ovariotomy," a case of sarcoma of the ovary furnishing him with the text.

Space will not allow us to mention several other papers of interest and the description of pathological specimens and conditions, all of which go to show that valuable work has been done in the society during the past year.

GOUT, AND ITS RELATIONS TO DISEASES OF THE LIVER AND KIDNEYS. By ROBSON ROOSE, M.D., F.C.S. Third edition, pp. 164. London: H. K. Lewis. 1887.

THE writer places before the reader a fine monograph on this subject, dealing with its pathology, discussing the uric-acid theories, relating the causes and symptoms, and giving the treatment and diet with which to cope with this aristocratic disease. The fact that the third edition is now before the public is proof of its value.

THE SCIENCE AND ART OF OBSTETRICS. By THEOPHILUS PARVIN, M.D., LL.D., Professor of Obstetrics and Diseases of Women and Children, in Jefferson Medical College, Philadelphia, etc. Illustrated with two hundred and fourteen wood-cuts and a colored plate. Philadelphia: Lea Brothers & Co. 1886.

THE author of the work before us has endeavored to write a clear and complete exposition of the science and art of obstetrics, and one which will be useful alike to students and practitioners—at least, so we are assured in the stereotyped phraseology of Dr. Parvin's preface. A careful examination of the book has failed to convince us of the necessity for its appearance. Aside from several standard English treatises, such as those of Barnes, Playfair, Leishman, we have the American works of Lusk, King, and Glisan, any one of which is at least equal to the volume prepared by Dr. Parvin.

It seems that the author is unduly impressed with the importance of French publications. The scant reference to the teachings of German writers constitutes, indeed, a noticeable feature of Parvin's obstetrics, thus forming a striking contrast to the able and scholarly treatise of Lusk. It is not always odious to compare, especially when comparison is boldly challenged by the presentation of new books that do not clearly show some advance over those already in the hands of the profession. Now, in our opinion, King's manual is preferable to Parvin's, on the score of condensation, precision, and positive teaching. Glisan's work, though less reliable for students, will be found more suggestive and more original. The English works are all more complete and thorough. The sum and substance of our criticism, then, is simply this, that the book before us was not needed at the present time, because we are already supplied with an abundance of excellent works on the same subject.

RESEARCHES UPON THE VENOM OF POISONOUS SERPENTS. By S. WEIR MITCHELL, M.D., and EDWARD S. REICHERT, M.D. Washington: Published by Smithsonian Institute. 1886.

THIS volume, which forms one of the series of the Smithsonian contributions to knowledge, is a valuable addition to what has hitherto been known as the subject of reptile poisons. By means of the snake-loop, as it is called, an ingenious device for seizing a serpent by the neck, it has been possible to collect venoms, to forcibly feed the reptiles and keep them alive for a longer period than heretofore. The authors have experimented with venom on birds and animals and reached the following important conclusions: That venoms bear a strong resemblance to the saliva of vertebrates; the active principles are contained in the liquid parts only. Micrococci are constantly present in fresh saliva, but have nothing to do with its violence. Dried venoms will retain their toxic properties for a long time. The toxic properties are globulines and peptones. The local effect of venoms is powerful, producing œdema, swelling, infiltration of the parts, and sloughing. It renders blood incoagulable. It softens the walls of blood-vessels so that they are unable to resist the normal blood pressure, and the blood exudes *en masse*. The shape of the red blood-corpuscles is changed; they become spherical, softened, and fuse themselves together into irregular masses. The direct action of venom on the nervous system is little, except that upon the respiratory centres, which it paralyzes. Death may occur through the paralysis of the respiratory centres, paralysis of the heart, hemorrhages into the medulla, and the altered condition of the blood-corpuscles. The respiratory centres are the most vulnerable.

Potassic permanganate, ferric chloride in the form of liquor or tincture, are the most available local antidotes. The fact that the active principles of venoms are proteids, and closely related to the normal constituents of the blood, renders it almost hopeless to search for a chemical antidote which can prove available after the poison has entered into the circulation. A physiological antagonist, therefore, is what must be sought. The investigators speak of the possibility of this discovery in a discouraged manner: "The activities of venoms are manifested in such diverse ways, and so profoundly and rapidly, that it does not seem probable that we shall ever discover an agent which will be capable at the same time of acting efficiently in counteracting all the terrible energies of these poisons."

MANUAL OF OPERATIVE SURGERY. By JOSEPH D. BRYANT, M.D., Professor of Anatomy and Clinical Surgery, and Associate Professor of Orthopædic Surgery, Bellevue Hospital Medical College; Visiting Surgeon to Bellevue Hospital; Consulting Surgeon to the Bureau of Medical and Surgical Relief of Bellevue Hospital; Consulting Surgeon to the New York Lunatic Asylum, and to the Northwestern Dispensary. With about eight hundred illustrations. New York: D. Appleton & Co. 1887.

THIS is in reality a second edition of this very practical work, the first having been published in different shape by another house. It has, however, been apparently in part rewritten, and bears proof of careful revision, both as to language and arrangement of the headings, thus greatly enhancing its value. The illustrations are more numerous, and those of the former edition which have been retained have been so retouched and lightened as to be worthy of the text and a real assistance in the comprehension of the operations described. The type and the paper are good, and the work is now presented in such a shape that it is a pleasure to study it. The subject-matter is excellent, and the author shows that he is not only a master of his art, but, what is equally important, possesses the not too common faculty of being able to impart his knowledge to others. We know of no better work on operative surgery to place in the hands of the student or of the young surgeon, and we cannot but congratulate the author upon the very presentable form in which his book is now offered to the profession.

OLFACTORY ACUTENESS.—Nicholls and Bailey have recently published the results of experiments upon the relative acuteness of the sense of smell in individuals. A series of solutions of oil of cloves, nitrite of amyl, extract of garlic, bromine, and prussic acid were prepared by successive dilutions with water until the limit of perception was reached, and then the solutions were placed indiscriminately and submitted to a number of persons of both sexes to classify them properly by the sense of smell. The results showed that on the average the sense of smell was much more delicate in the males tested than in the females; but the degrees of keenness ranged widely as between individuals. Thus three male observers were able to detect one part of prussic acid in 2,000,000 parts of water, though its presence was not revealed by a chemical test; but others, of both sexes, could not detect prussic acid in solutions of almost overpowering strength. The following figures give the average limit of delicacy of perception: Cloves—Males, 1 in 88,128; females, 1 in 50,667. Nitrite of amyl—Males, 1 in 783,870; females, 1 in 311,330. Extract of garlic—Males, 1 in 57,927; females, 1 in 43,900. Bromine—Males, 1 in 49,254; females, 1 in 16,244. Prussic acid—Males, 1 in 112,000; females, 1 in 18,000.—*Medical Press.*

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 7, 1887.

A. JACOBI, M.D., PRESIDENT, IN THE CHAIR.

DR. A. J. C. SKENE'S memorial paper on

H. W. DUDLEY, M.D.,

was read by DR. THALLON, of Brooklyn, and was an excellent tribute to the memory of a most worthy member of the medical profession.

DR. ARPAD G. GERSTER then read a paper (see p. 453)

ON THE PROPER SELECTION OF ETHER OR CHLOROFORM AS AN ANÆSTHETIC.

The discussion was opened by the reading of the following letter from DR. H. KNAPP, addressed to the President:

"I regret to be prevented from attending the meeting of the Academy this evening, and, in compliance with your request, to take part in the discussion of Dr. Gerster's paper. If I may be permitted briefly to state my personal experience with chloroform and ether, it is as follows:

"From 1860 to 1874 I used chloroform in over three thousand cases. There was no fatal result, but many unpleasant and a certain number of critical cases. About once a month I had to resort to artificial respiration and other means of resuscitation. Having seen fatal cases in Berlin and Vienna, I was in constant dread.

"From 1874 to this day I have used ether in all cases of anæsthesia, in children as well as in adults, in drunkards, in persons affected with lung and heart diseases. No general complaint has been considered a contraindication. I have administered ether according to the so-called 'choking plan,' yet admitting of so much air at the beginning as to let the patient get over the impression of asphyxia. A great many of the operations that I had to perform could be finished during the period of primary anæsthesia; others lasted for hours, during which time the narcosis was kept up uninterruptedly.

"In several hundreds of successive etherizations I have taken notes of the course of the narcosis. The average time to bring about anæsthesia was *one minute and thirty-seven seconds*. There has been no fatal case, and only very few in which I had to interrupt, temporarily, the narcosis; none, as far as I recollect, in which it had to be relinquished. The secondary effects have not been more unpleasant than from chloroform. I use ether as the universal anæsthetic, consider it safer than chloroform, and just as manageable, if not more. Since I employed it my mind has been free from the anxiety which in chloroform I could never overcome."

DR. WEIR continued the discussion, and remarked that Dr. Gerster's paper conceded the important fact that chloroform was more dangerous to life than ether. But even admitting for a moment the additional risks that are said to come to an etherization from pneumonia and kidney complications, is the danger of the two anæsthetics at all equalized thereby? He thought not, decidedly not. The statistics, imperfect in many ways, go strongly against chloroform; the collection of Roberts from 1873 to 1880 gives but eighteen deaths from ether obtained from all sources all over the world. In the same period were collected in a similar manner by Turnbull ninety-two cases of deaths from chloroform. Moreover, a single journal, the *Lancet*, published in eighteen months, *i.e.*, from January 1, 1869, to July 1, 1870, seventeen deaths from the latter anæsthetic. He, in his turn, felt impelled to admit that ether was more dangerous than is supposed, due mainly, he thought, to

THE RECKLESS WAY IN WHICH IT IS GENERALLY ADMINISTERED,

and particularly in our large hospitals. As to the pneumonia which it is said to produce, he felt, while not denying it, that perhaps other reasons for this complication could be set forth, and the principal one was the undue exposure and cooling of large portions of the body during operations. Lung complications became more noticeable with him when antiseptics came into use, from the spray, and latterly from the incautious employment of the wet antiseptic towels and cold rubber cloths. Furthermore, he was unwilling to accept the dictum that a *pre-existing kidney disease contraindicated the use of ether*. He had, as most surgeons had, been compelled often to operate in such conditions, and since the articles of Emmet, Hunt, and others had called attention to the possibility of augmentation, not creation, of kidney trouble from the use of ether, he had taken more care in these cases to give ether carefully and moderately, and to keep his patient warm and free from exposure and draughts, and so far he had escaped mishap.

He individually could only speak of one serious result from ether anæsthesia. This occurred in a man who came into the New York Hospital in 1884, with symptoms of rupture of the bladder and commencing peritonitis. As the case was urgent he was immediately etherized, and an incision below the umbilicus begun. Vomiting occurred, and the patient became cyanosed and ceased to breathe. The autopsy showed a piece of undigested food from a recent meal to be lodged in the larynx.

Dr. Weir further stated that the whole number of deaths from ether in the old New York Hospital, from 1850 to 1870, out of about seven thousand seven hundred operations, was three. One occurred in the service of the late Dr. Allen, and has been already reported—and followed the first incision for a tumor of the jaw (an irritation which Schiff has shown will often arrest respiration). The second happened during an operation by Dr. Markoe for strangulated hernia, the man's head being very low down in the bed, the hips having been elevated to facilitate the re-entrance of a large mass of intestine to the abdominal cavity. The third took place in 1860, under the charge of Dr. Bell, the house surgeon, who reduced under ether a very large double scrotal hernia which, not previously reducible, had become incarcerated. No cause for the death was revealed by the autopsy, and it was believed that the replacement of

THE INTESTINES INTO THE LONG-EMPTIED ABDOMEN

had interfered with the diaphragm and heart-action. Since the rebuilding of the New York Hospital in Fifteenth Street, in 1876, there have been performed 2,289 operations, with 2 deaths from ether—one of which, his own, has already been given; the second of this series was met with in 1882 in a case of extravasation of urine. On making incision into the perineum, death suddenly came on. The autopsy showed a fatty heart. In the House of Relief (a branch of the New York Hospital) there have been, since 1876, 802 operations, with 1 ether death. This was encountered in 1886. While operating (under ether) on a man with crushed fingers, it was noticed that the venous oozing suddenly ceased, and death followed in a few minutes. A post-mortem examination revealed tubercular lungs and an atheromatous aorta. Summing up this experience, which represents one of the largest hospitals in the country, there are found 6 deaths from ether in 10,791 administrations, or 1 death in 1,796 cases; or, if the choking case is eliminated, there would be 1 death in 2,158 cases. Dr. Weir thought that this experience would more or less be confirmed by other hospitals should they publish their cases, though a sharp distinction should be made in the cases of deaths from ether and those dying during etherization.

Nevertheless, while admitting, as before stated, that ether was dangerous, and more so than is usually estimated, yet, had he to be operated on, and had he, moreover, damaged kidneys, he would think himself safer under anæsthesia from ether than if chloroform was used.

Dr. Lewis A. Sayre continued the discussion (see p. 458).

Dr. W. Gill Wylie said that his experience had been favorable, and that he had not lost a patient during or very near to the time of the operation until quite recently, when his experience had been rather sad. Within two months he had lost two patients who had been anæsthetized with ether, and their deaths, he thought, could be attributed directly to the anæsthetic. He could accept almost all that Dr. Gerster had said, except that he would reverse the statement, and say that he would prefer to give ether on account of its being safer, but that in a certain number of cases chloroform should be used. He believed that Dr. Gerster was perfectly correct in regard to what he had said concerning

THE RECKLESSNESS WITH WHICH ETHER IS GIVEN IN MANY PUBLIC INSTITUTIONS.

Dr. Wylie was certain that it was true of some institutions in New York. In the lying-in room he used chloroform, and he had never had any accidents with it. He had reached these conclusions: The frequent repetition of ether created in the person a tolerance which was sometimes very unpleasant when general anæsthesia was desirable. In very fat persons anæsthetics were especially dangerous. Three or four years ago he favored the use of ether in almost all cases. Now he would, as a rule, use ether; but in many cases, especially if the kidneys were affected, or there was reason to suppose that the lungs were seriously affected, he would prefer chloroform. He would always use chloroform in the lying-in room, and generally in children. Dr. Wylie then detailed his two fatal cases; one was an umbilical hernia in a very fat person, and the other a case of abdominal tumor, in which, before the operation, the urine gave no evidence of kidney disease, but the autopsy revealed chronic interstitial nephritis with an acute attack.

Dr. Weir believed that all peritoneal operations should be excluded when collecting deaths from ether.

Dr. John A. Wyeth had formulated his views regarding ether and chloroform as follows: Chloroform must be preferred in almost all operations in children under *six* years of age, and in women during childbirth. Chloroform may be preferred to ether when ether has been tried without producing anæsthesia. Chloroform may be used when ether cannot be obtained. With the exception of nephritis, he had not seen any reason for changing these conclusions.

He had almost always used ether in both hospital and private practice, and during the last eighteen years he had not had an accident from it, certainly not a death. He had not met with the class of cases described by Dr. Gerster—namely, that in which the patient resists anæsthesia so much that chloroform must be substituted for ether. Nor had he encountered pneumonia. He thought that there was danger from pneumonia after all prolonged operations, and that in one of Dr. Gerster's cases, in which

THE OPERATION LASTED SIX HOURS,

the same pulmonary complication might have occurred if chloroform had been used. He believed that Dr. Sayre's success in the use of chloroform could be accounted for largely on the ground that he had used it more in children and in cases of parturition than in other cases.

With regard to statistics, he had found in "Agnew's Surgery," second volume, a careful analysis of all the deaths that had occurred from ether and chloroform from 1869 to 1872, and there were one hundred and ninety-five from chloroform and six from ether. In three of those charged to ether the E. C. mixture was used, and these three fatal cases Dr. Agnew eliminates.

Dr. Robert Abbe had seen one death from ether. There was a compound fracture of the leg, and the patient had tetanus. Dr. Little proceeded to amputate under ether. The patient died upon the table, with intense rigidity of the whole body. He believed that the danger from pneumonia or acute bronchitis, and from nephritis, were under the control of the surgeon, while

THE DANGER FROM CHLOROFORM IS ABSOLUTELY BEYOND THE CONTROL OF THE SURGEON

in a considerable proportion of cases. He believed that the pneumonia and bronchitis referred to were due to exposure of the patient. He had operated under ether, in cases of necessity, and without disaster, although the urine contained albumen and casts.

Dr. Mundé had used both ether and chloroform extensively, but had not seen any deaths that could be referred to the anæsthetic. He had, however, seen three cases abroad—one in a man, the other two in children—where chloroform was administered, and only the most active and decided measures saved the patients from death.

In two cases, after prolonged operations under ether and on lifting the patient up, he had seen syncope, which he felt quite certain would have proved fatal had not very active measures been adopted. His feeling was, after having been bred abroad to use chloroform, that

ETHER IS THE SAFER OF THESE TWO ANÆSTHETICS

when properly administered. He felt that the remarks of Dr. Gerster regarding the recklessness with which anæsthetics were given were highly commendable. In hospitals it was generally left to those who were last admitted *and the least qualified* to perform what was one of the most important duties connected with a surgical operation, which was all wrong. The administration of the anæsthetic should be intrusted to skilled persons only. In all long operations he preferred to use ether, and with Clover's inhaler. He had noticed that, in some cases, it was impossible to get the patients under the proper influence of ether, and it was only when he had changed to chloroform that they had been properly anæsthetized. He had almost always given a bromide salt, but sometimes a hypodermatic injection of morphine before beginning the anæsthetic.

For short operations he preferred chloroform, and also in obstetrics, except where he wished to stimulate uterine contractions in tedious labor.

Dr. R. W. Amidon noticed that the writer of the paper had stated that the only contraindication to chloroform was a weak heart, but at the same time it was well known that death occurs unexpectedly and much more so than when ether is given, in by far the greater majority of cases. That had been stated as well by Dr. Reeve as anyone, in Holmes' "Surgery," who says, "It is one which no far-sightedness can discern, no precaution can avoid, no skill avert." Another point to which Dr. Gerster had very properly called attention was

THE DISADVANTAGE IN THE USE OF ETHER FROM THE COLLECTION OF MUCUS IN THE AIR-PASSAGES.

Dr. Amidon thought that if the precaution was taken to use the prophylactic measure to which he had called attention, that is, preliminary injection of one-sixtieth to one-fiftieth of a grain of sulphate of atropia, or by the mouth some preparation of belladonna, that the respiratory act would be improved and that the bronchial and tracheal secretion would frequently be lessened, and the disadvantages arising from ether, in this particular, would be substantially done away with. He believed that this precaution had been used by Dr. Weir and by Dr. Thallon, with good results.

Dr. Thallon, of Brooklyn, said that he had listened

with a great deal of interest to the paper of the evening, and yet it had impressed him as one that was somewhat one-sided. He quite agreed with Dr. Weir that ether was not absolutely contraindicated by the presence of albumen and casts in the urine, but the presence in the urine of these evidences of kidney disease should make the surgeon

MORE CAUTIOUS IN THE ADMINISTRATION OF ETHER.

The question of the use of either or chloroform was largely one of dosage, and he preferred the ordinary apparatus used by dentists, with which the patient, very much as with Dr. Sayre's apparatus, breathes the air impregnated with the anæsthetic and expires the foul air through another opening. He had never had the trouble of which Dr. Gerster had spoken; that is, the patients kicking around the table, and he had given anæsthetics many hundreds of times. He believed that the bad effects of ether were due largely to the ignorant and indiscriminate way in which it was used. He first noticed in the *Lancet* the use of atropia before beginning the inhalation of ether, and he had used it with so much benefit that he had practised carrying a solution of it in his pocket or case, and administering it as a prophylactic, especially against undue secretion of mucus in the respiratory tract.

Dr. Gerster, in closing the discussion, said it was very strange, after having tried to appear unbiassed, that he should be charged with partiality, as he had been, by nearly all who had spoken with the exception of Dr. Sayre. He was not astonished at it, however, because everyone of the gentlemen who had spoken was evidently one-sided, and his position as stated in his paper had been entirely misunderstood.

He said, and still maintained, that it was one-sided to say that chloroform was the only anæsthetic that should be used, just as it was unsound to claim that ether was the only anæsthetic to be employed.

He regarded ether as the less dangerous of the two in the general run of cases. But the hospital surgeon who operates every day, and perhaps on many cases, will encounter many more cases in which it is not only difficult, but impossible, to produce the desirable complete relaxation with ether, than those who have occasion to give an anæsthetic only a few times in a year, and he would repeat that there are patients who cannot be brought into complete anæsthesia with ether, even though administered by Dr. Thallon himself. Under such circumstances

THE SURGEON MUST USE CHLOROFORM,

and he is a poor surgeon if he is afraid to use it, as many of the gentlemen seemed to be. He did not say that he would use chloroform in all cases, but would use ether, as the rule; but where there were present the contraindications which he had enumerated, he would employ chloroform, and surgeons should know how to use it and should not be afraid to use it.

With regard to statistics, he would not give *five* cents for all that had been brought forward; they were worthless. He was aware that deaths from chloroform had been hunted up, and he also knew of a number of deaths upon the table from ether that had never been reported, and never would be published. He knew of *five* cases of death from ether in *one* hospital which had not been published. There was no doubt about deaths occurring on the third, fifth, and sixth days, etc., from nephritis or pneumonia after anæsthesia by ether, and yet these cases were not reported. Therefore the statistics given by Dr. Weir did not have the merit of truth which they should have in order to be reliable. If the absolute number of deaths from all anæsthetics could be ascertained, then proper conclusions could be drawn concerning the relation and the comparative safety of each one. Therefore, he believed that the argument by statistics should not be admitted in the discussion of so serious a question.

With regard to the occurrence of *pneumonia*, he had also been misunderstood. He did not understand that the pneumonia and bronchitis were due to the inhalation of cold vapor or exposure of the patients in the corridors or wards of hospitals, or in operating-rooms. He believed that there was a much more direct

INSULT TO THE RESPIRATORY TRACT

in the mucus that had collected and undergone change. Before the inhalation of ether the breath of the patients might be sweet, but having been anæsthetized it was not uncommon for it to have an odor of decomposition that was a source of great discomfort to those who came near them, and this decomposing mucus in the oral cavity and trachea finding its way into the lungs was the much more probable cause of the bronchitis and pneumonia than the inhalation of cold vapor or the exposure referred to. In the presence of micro-organisms in the buccal cavity and stomach rapid decomposition of mucus might take place, even during the production of anæsthesia, and this mucus was very liable to be drawn into the lungs.

He had tried to say that both ether and chloroform were used extensively as anæsthetics. If used intelligently and properly they are ordinarily safe. Sometimes fatal results will follow one as well as the other. These were facts admitted by both the advocates of ether and of chloroform.

He had endeavored to show that the entire question of the greater safety of the one over the other rests upon opinion, as there had not been brought any absolute proof that either ether or chloroform was the safer or the more dangerous. So long, therefore, as the question must remain as a matter of opinion, was there justice or common-sense or fairness in the position taken by many physicians by saying that anyone who administers chloroform for general *surgical* anæsthesia deserves criminal prosecution? Against that spirit he would beg to protest, and that was the real reason why he brought the subject before the Academy. So long as the question was an open one, he believed that the Academy should protest against such a view.

The Academy adopted the report of the Council that it had had under investigation charges made against a Fellow for giving a certificate which subsequently had been published extensively as an indorsement of a proprietary medicine, and recommended that the Fellow be informed that the writing of such

A CERTIFICATE WAS OBJECTIONABLE.

The Academy then adjourned.

Formulæ for Lanolin Salves.—The manufacturers of Dr. Liebreich's lanolin salves have published a list of formulæ for their preparation. The following are some of them: 1. Unguentum belladonnæ: Extr. belladonnæ 5.0, lanolini 45.0. Unguentum potassii iodidi: Potassii iodidi 20.0, aqua 10.0, adipis sulli 20.0, lanolin 150.0. 3. Unguentum carbolic.: Acid. carbolic. 5.0, adipis 5.0, lanolini 90.0. 4. Unguentum acid. pyrogallic.: Acid. pyrogallic. 10.0, adipis 10.0, lanolini 80.0. 5. Unguentum acid. salicylici: Acid. salicyl. 10.0, adipis 20.0, lanolini 70.0. 6. Unguentum hydrarg.: Hydrargyri 50.0, lanolini 12.5, ung. hydrarg. 2.5. 7. Unguentum iodoformi: Iodoformi 10.0, adipis 10.0, lanolini 80.0. 8. Unguentum chrysarobini: Chrysarobini 10.0 to 25.0, adipis 10.0, lanolini 80.0. 9. Unguentum picis liquid.: Picis liquid. 20.0, lanolini 80.0. 10. Unguentum ichthyoli: Ichthyoli 10.0, lanolini 90.0.

Veratrum in Pneumonia.—Dr. J. W. Maddin, of Nashville, makes a plea for the use of veratrum viride in pneumonia, to be used in the stage of engorgement always, and never after this period.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE SOCIETY OF APOTHECARIES AND THE "CONJOINT SCHEME"—SOME CASES OF RENAL DISEASE—INCISING THE OPTIC SHEATH FOR SWOLLEN DISK—DR. BROADBENT ON THE PULSE.

LONDON, March 28, 1887.

As was anticipated, the two colleges have refused to allow the Society of Apothecaries to combine with them and thus to become a party to the "conjoint scheme." The earnest recommendation of the medical council has availed for naught. That body, indeed, has sowed the wind and is now reaping the whirlwind. Its vapid utterances in former times have so discredited it in the eyes of the profession and the governing bodies of the various corporations, that its protest now passes unheeded. The consequences in the present instance will be that the Society of Apothecaries will obtain the power to give a complete diploma, and an inferior grade of general practitioners will be inaugurated who will compete with the holders of the "conjoint diploma," very much to the disadvantage of the latter.

Several interesting cases of renal disease have lately been brought before the societies. At the last meeting of the Medical and Chirurgical Society, Mr. Godlee read a paper in which he gave the history of a unique case of renal calculus causing suppression of urine. The remarkable feature of the case was that the suppression was complete, but the calcular disease was only on one side. After acute pain in the right loin and other symptoms of renal disorder a perinephritic abscess formed on the right side, and was opened. The kidney could not be found at the operation. The casts disappeared completely from the urine, and the albumen became very small in amount. The wound healed and the patient remained well for a time. A year later he was seized with a severe attack of renal colic and in a few days complete suppression of urine supervened.

No operation was undertaken, because it was assumed that there was only one working kidney, the ureter of which had become blocked. After the suppression had lasted five days, however, the left kidney was felt and punctured, but its pelvis was found to be empty. Two days later the patient began to pass highly albuminous urine. This became more normal day by day, but the patient died exhausted in less than a week. At the autopsy the right kidney was found to be dilated into a loose bag of pus and a stone was impacted half-way down its ureter. The latter, however, was dilated throughout its whole extent. The left kidney was large and comparatively healthy, except that it showed signs of chronic interstitial nephritis. The pelvis and ureter on the left side were normal.

Mr. R. W. Parker read a paper on a case of suppression of urine following injury to a sacculated kidney containing calculi, the other kidney being entirely disorganized.

At the Medical Society Dr. Ralfe showed an oat-shaped calculus (chiefly composed of oxalate of lime) which had been passed after six weeks' treatment. It was a third of an inch in length, and weighed three grains and a half. The treatment employed was the administration of a mixture containing lithia and turpentine. Dover's powder was given at night. The patient was also directed to drink three pints of filtered rain-water daily. Under this régime the specific gravity of the urine fell from 1.025 to 1.014, blood and pus disappeared from it, and the attacks of renal colic became less frequent. Dr. Ralfe remarked that his method differed from that of Sir William Roberts in that he did not seek to lessen the size of the calculus by chemical solvents, but by checking its growth, reducing the specific gravity of the urine, and diminishing existing pyelitis, to allow free passage to the concretion. There were many calculi, said Dr. Ralfe, that were small enough to slip down a ureter, but they were prevented by the swollen condition of the orifice. In addition to distilled water and turpentine he also thought highly of benzoate of lithia or potash.

At the same meeting of the Society Mr. Brudenell Carter read a paper on a case of swollen optic disk, in which he had, by a new operation, incised the sheath behind the eyeball. The patient was a young woman who sought advice for headache and impaired vision in the left eye, of ten days' duration. On ophthalmoscopic examination the optic disk was found much swollen. Iodide of sodium and mercurial inunction were prescribed, but without benefit. The swelling increased, and hemorrhages appeared in it. Mr. Carter then divided the external rectus muscle, rotated the eyeball inward, exposed the nerve, and, opening its sheath, let the fluid exudation escape. The patient made a good recovery and the symptoms disappeared. Sight had begun to return in the previously blind temporal half of the field. Mr. Carter remarked that De Wecker had in 1872 unsuccessfully attempted to open the sheath without the aid of sight by employing a specially curved knife. The method he had himself employed (of previously dividing the muscle) allowed the operator to see what he was doing, and the procedure could be carried on without danger.

In his recent Croonian Lectures at the College of Physicians Dr. Broadbent has been discoursing on "The Pulse," a subject to which he has devoted much attention. Although one of the early workers with the sphygmograph, he has not a very high opinion of its clinical value, as it requires considerable skill and experience to use it to advantage. He remarked: "It is rarely necessary for diagnosis, and scarcely ever to be trusted in prognosis." The pulse was not, he said, as commonly stated in text-books, an expansion of the artery; nor was it a sinuous movement of the vessel in its bed. It was the change of shape from the flattened condition impressed upon the artery by the finger, or by the sphygmographic lever, to the round cylindrical shape which it assumes under the distending force of the blood within it, that constituted the pulse that we observe clinically. It was a misconception to suppose that the pulse signified onward movement of the blood in the artery. Remarking on the fact that for all ordinary purposes we took the pulse at the wrist, Dr. Broadbent remarked that, as a matter of observation, we knew that the pulse at the wrist indicated the state of the circulation generally. The fact, also, that the hand had no special circulation of its own liable to extreme variations for functional purposes, made the radial pulse more trustworthy.

OUR PARIS LETTER.

(From our Special Correspondent.)

HYPNOTISM AND MENTAL SUGGESTION.

PARIS, April 1, 1887.

"SUGGESTION" is decidedly taking its place in the domain of clinical therapeutics, and it has even passed the threshold of the Faculty of Medicine, in proof of which we have only to refer to the recent works of Dr. Gilles de la Tourette, and of Professor Bernheim, of Nancy. In his preface the latter author gives the following definition of suggestion: "Suggestion, which dominates the greater part of the manifestations of hypnosis, the pretended physical phenomena, is nothing else than psychical phenomena. It is the idea conceived by the operator, which, seized by the hypnotized subject and accepted by his brain, realizes the phenomenon, favored by an exalted suggestibility, produced by the special concentration of the hypnotic state." In other words, suggestion signifies the penetration of the idea of the

phenomenon in the brain of the hypnotized subject by speech, gesticulation, sight, imitation. We are far from the empirical interpretations of animal magnetism and of mesmerism; with the aid of special fluids, they are nothing more than the phenomena of suggestion. This view would, moreover, give the key of Braidism, and somnambulism itself is only an advanced degree of hypnotism, or profound sleep, with unconscious suggestive phenomena. Professor Bernheim could not help paying a just tribute to Dr. Liébault, of Nancy, who for the last twenty-five years has devoted himself with the greatest disinterestedness and courage (for he has had to brave a good deal of sarcasm and ridicule) to the study of the treatment of maladies by sleep, confessing at the same time that having for a long time been himself sceptical, he yielded only after having been convinced by the hypnotic cure of a hystero-epileptic subject, affected with contracture of the right leg of three months' duration, and at the same time subject to convulsive attacks which were renewed five or six times a day. Professor Bernheim's work is composed of two parts. In the first part the author treats of the different degrees of hypnotism which his method can produce (they are six in number), and he analyzes the different phenomena presented by the hypnotized subjects, among the most curious being post-hypnotic suggestions in somnambulistic subjects, with unconsciousness at waking.

The suggested acts, explains the author, sometimes meet with resistance on the part of those who are subjected to them, but in general they are entirely accomplished. The same is the case with sensitive sensorial suggestions, and with simple or complex hallucinations which may be provoked. In a very important chapter of the work the author treats of the subject in a moral and psychological point of view, and examines the relations of suggestion with the civil and criminal laws, the hypnotizer deserving all the severity of the law without extenuating circumstances, the responsibility of the hypnotized subject being almost completely annulled. In the second part of the work the author treats of suggestion applied to therapeutics; in other words, the imagination as a curative agent. Nobody has ever denied the efficacy of this powerful factor, and it is to its influence that should be attributed the credit of thaumaturgists and healers of disease by verbal assurance, who still work on the credulity of the ignorant. To provoke by hypnotism this special psychical state, and to operate, in view of cure and of relief, the suggestibility thus artificially excited, such is the rôle, according to M. Bernheim, of psycho-therapeutical hypnotics. The action of remedies at a distance, referred to in your note on the subject in THE MEDICAL RECORD of March 19th, would be an exemplification of mental suggestion. As a general rule, states the author, the action obtained is more rapid and more complete with profound sleep. It is, therefore, in somnambulism that suggestion acquires its maximum of efficacy, that cures are often instantaneous and assume a miraculous appearance. The numerous cures which are affected each year at the grotto of Lourdes, a place of pilgrimage in France, cannot have any other explanation, according to the same author, than religious auto-suggestion, in very narrow relation with hypnotic suggestion, but as he does not wish to attack religious faith, nor injure religious sentiments, he has manifested a praiseworthy circumspection in this respect. He has published in detail the cases of seventy-one patients in proof of his assertions, and which he considers are sufficient to induce others to adopt this new therapeutical method. The case of permanent cure of writers' cramp by patient and persevering suggestion appears to be the most remarkable.

At a recent meeting of the Academy of Medicine, Dr. Rochard exhibited, on the part of Dr. Mondot, of Oran, an entire tibia which was removed in December last from a woman aged thirty, a scrofulous subject, who was affected with suppurating osteitis of that bone. The periosteum was detached in its entirety and the bone was sawn off with a chain-saw. A new tibia was reproduced, and two months after the operation the patient was able to walk about, which she still does, with the aid of a boot made specially for her.

Dr. Doleris, a rising accoucheur, has performed a certain number of experiments which show that injections of corrosive sublimate into serous cavities, and that the washing of wounds with this substance, even in the proportion of 1 to 1,000, are eminently toxic. The accidents by which this intoxication are manifested are: Lowering of the body temperature, colliquative diarrhœa, considerable weakening of the muscular system, albuminuria, etc. The conclusion arrived at by the author, which he recently communicated to the Biological Society of Paris, is that the corrosive sublimate, which is an excellent antiseptic, ought to be reserved for the disinfection of the skin, the hands, instruments, and in a general manner for all articles of dressing, but for the washing of wounds and of large serous and mucous surfaces, it should be absolutely proscribed.

"SEXUAL PHYSIOLOGY AND MOHAMMEDAN WOMEN."

To the Editor of The Medical Record.

SIR: In your issue of February 12th, p. 192, is a short article entitled: "Sexual Physiology and Mohammedan Women," which makes certain assertions on the authority of Dr. Zambaco. These statements may all be true for the Mohammedans among whom the doctor lives, but many of them do not hold good for those of Syria. I have lived here for several years and have carefully inquired of other physicians into the subject, but in no case have I ever heard of a girl being circumcised. I have been told that in Egypt the operation is performed. Marriages take place at a very early age, not only among Mohammedans but among all Christian and other sects, though it must be remembered that the girls of the East are several years in advance of those of the West in point of physical development. I have been told on good authority of a woman of Damascus who was a grandmother at the age of twenty-one.

In consequence of these early marriages, probably, fecundity is rare; for abortions are rare, and it is the wife's highest ambition to bear her husband a son. Sterility is as great a cause for reproach as it was among the Jews of old, and it is a common cause of divorce or of the husband's taking a new wife. The honor attached to having a son is so great that the mother frequently loses her identity and is known as the mother of such a one, *e.g.*, Im Amin—the mother of Amin. Uterine disorders may be common, but they are not known to the physician, as he has no access to the females, married or unmarried.

It must be remembered that the Mohammedans number some two hundred millions, thirty millions of whom are under Turkish rule, while the others are found in Persia, India, and Africa, extending from Egypt to about the great lakes, so no one rule can be given to cover all these people. Truly yours,

THOMAS W. KAY, M.D.

BEYROUT, SYRIA, March 14, 1887.

THE ANTIQUITY OF PRESERVATIVE INJECTIONS.

To the Editor of The Medical Record.

SIR: In your summary (MEDICAL RECORD, March 12th, p. 302) of Dr. Laskowski's work on embalming, etc., it is stated that: "It was not until the present century that embalming and the preservation of subjects was undertaken by means of injections into the vessels. Dr. Franchina [Tranchina], of Naples, and, almost at the same time (1835), Lauth, of Strasbourg, conceived the idea of

forcing preservative fluids into the blood-vessels." As a matter of history, in 1775, sixty years before these attempts at preservation by Tranchina and Lauth, Dr. Wm. Hunter, assisted by Cruikshank, injected turpentine and spirits of camphor into the femoral and other large arteries, for the purpose of preserving the body of a woman; and the operation is spoken of as if it were not an absolutely new proceeding even then (Pettigrew's "History of Egyptian Mummies," London, 1834, p. 258, and Dr. Wm. W. Keen's "History of Practical Anatomy," Philadelphia, 1874, p. 36).

In your summary ought not the name "Gaunal" to be Gannal, and "Franchina" to be Tranchina?

Yours,
S. H. GAGE, M.D.

CORNELL UNIVERSITY, ITHACA, N. Y., March 22, 1887.

[The systematic use of preservative injections dates at the period we mention.

Gannal is the proper name, not Gaunal, as our printers made it. Franchina is the name given by Laskowski.—ED.]

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 10 to April 16, 1887.

RICHARD, CHARLES, Captain and Assistant Surgeon. Granted two months' leave of absence on surgeon's certificate of disability. S. O. 82, A. G. O., April 9, 1887.

KANE, JOHN J., Captain and Assistant Surgeon. Resigned April 13, 1887. S. O. 85, A. G. O., April 13, 1887.

WALKER, FREEMAN V., First Lieutenant and Assistant Surgeon. Ordered from Fort McIntosh, Tex., to Post of San Antonio, Tex. S. O. 45, Department of Texas, April 11, 1887.

APPOINTMENTS.

CABELL, JULIAN M. To be Assistant Surgeon with the rank of First Lieutenant, to date from April 14, 1887.

WOODRUFF, CHARLES E. To be Assistant Surgeon with the rank of First Lieutenant, to date from April 14, 1887.

The Army Medical Board, New York City, N. Y., is dissolved. S. O. 82, A. G. O., April 9, 1887.

Official List of Changes in the Medical Corps of the United States Navy for the week ending April 16, 1887.

GRIFFITHS, S. H., Passed Assistant Surgeon. Detached from the U. S. S. Lancaster, and waiting orders.

HIBBETT, C. T., Passed Assistant Surgeon. Detached from duty on ironclads, City Point, Va., and waiting orders.

MARSTELLER, E. H., Passed Assistant Surgeon. Ordered to duty on ironclads, City Point, Va., the 20th instant.

PROFESSOR VERNEUIL still continues to teach at La Pitié, and is as full of vigor and energy as he was when I first heard him twenty years ago. My time had been so much occupied in other directions that I have not been able to follow him regularly. He has, however, a hobby which he is riding just now, and that is, the discussion of glandular tumors by the interstitial injection of a ten per centum solution of iodoform in ether. His results are apparently very good.—Cor. *Chicago Medical Journal.*

New Instruments.

AN IMPROVED OPHTHALMOSCOPE.

BY FRANCIS VALK, M.D.,

NEW YORK.

IN estimating the refraction of the eye, or the elevations and depressions that may occur at the fundus, the ophthalmoscope has become one of the most useful instruments in the hands of the ophthalmologist. This instrument has been subject to many changes and improvements until we have found almost the perfection of the ophthalmoscope in Dr. E. G. Loring's last design, which, in the arrangement of the glasses, their size and accuracy of refraction, and the large number of combinations, with the added quadrant, besides its neat, light, and mechanical workmanship, leaves almost nothing further to be desired.

In the use of this ophthalmoscope for the past four or five years, it has seemed to me that if some mechanism could be devised by which the various lenses could readily be brought behind the aperture without removing the instrument from the eye, so that the accommodation would more readily tend to relax in the estimation of hypermetropia, it would be a decided improvement, and one that would meet the approval of the profession.

With this object in view I have devised the instrument, or rather the improvement to Dr. E. G. Loring's instrument, as shown in the cut. This consists of a rectangular bar, connecting the ophthalmoscope with the handle, somewhat longer than the bar now in use; upon this bar is a slide with the lower part raised and roughened, so that it can be held steadily and firmly with the thumb and forefinger. This slide is made to pass freely up and down; passing upward from the slide is a flat rack of brass having on one side a series of small teeth, which act upon a cog-wheel attached to the disk containing the lenses. This cog-wheel motion is so set that when the slide is in the middle of the square bar, the aperture in the disk will be over the aperture in the ophthalmoscope.

It will readily be seen, then, that in the use of this ophthalmoscope, by simply pulling the slide downward, it will cause the disk to rotate to the right, thus bringing

the convex glasses successively behind the aperture; or by pushing the slide upward the concave glasses will be successively placed behind the aperture.

The small quadrant that contains the convex and concave glasses of 16 and .05 D is fastened to the segmented cover of the back of the ophthalmoscope by the two small seams in the centre, and when this is to be used, to obtain the stronger glasses, it is simply necessary, if convex glasses are needed, to put the +16 D over the aperture, then push the slide up to the top of the bar, and as it is pulled downward the convex combinations will successively be placed before the aperture from +8 D to +23 D; the same action of the slide with the −16 D behind the aperature will make all the combinations between −9 D to −24 D; only pull the slide down to the lowest point first, and then push it up.

I am inclined to think that by the use of this attachmen to Dr. Loring's ophthalmoscope the examination of the fundus and the estimation of the errors of refraction will be much more exact and satisfactory, as by the ease and ability by which we can bring these successive glasses before the eye will allow the examiner's accommodation to become easily relaxed in the estimation of hypermetropia, and also to more readily select the weakest concave glass in the estimation of myopia.

This instrument has been made for me by the firm of E. Gayler & Co., 839 Broadway, and I feel satisfied it will be found perfect in every respect.

Since writing the above I have learned from Dr. E. G. Loring that a similar movement was used on an ophthalmoscope with a single disk several years ago, and reported in Graefe and Saemish's "Handbook of Ophthalmology," vol. iii., part i., p. 135; but as the movement seems to me, since I have used it, an improvement in the method of using the ophthalmoscope, I have determined to present it to the profession. I would also add that this rack-and-wheel motion is so arranged that it can be easily applied to the Loring ophthalmoscope now in use.

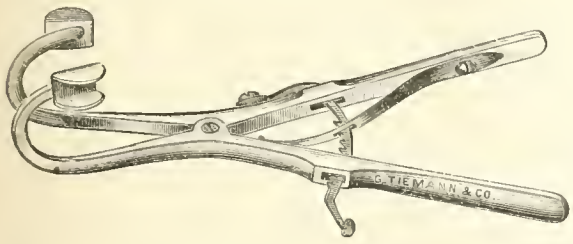
163 East Thirty-seventh Street.

A MODIFICATION OF O'DWYER'S GAG.

By CHARLES E. DENHARD, M.D.,

NEW YORK.

The following modification of O'Dwyer's gag I have devised to meet a serious objection to an otherwise excellent instrument. No matter how firmly the child's



head is held, the left shoulder is frequently forced against the arms of O'Dwyer's gag, thus displacing the instrument, to the physical discomfort of the physician's finger and possible laceration of the gums or the cheek of the little patient. In the modification, as will be seen in the accompanying cut, the arms of the lever are directed straight backward toward the ear, in place of being inclined down as in the original instrument. The assistant standing behind the patient can readily include the gag within his grasp while holding the head of the child. The catch also has been modified, the ring of the original being replaced by a dentated spring, allowing the jaws to be separated to the desired degree. The instrument has been used by myself and friend, Dr. Huber, in at least fifty instances with entire satisfaction.

90 Madison Street.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 16, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	4	2
Scarlet fever	58	13
Cerebro-spinal meningitis	5	5
Measles	101	10
Diphtheria	102	41
Small-pox	6	5
Yellow fever	0	0

Some Patent Medicine Formulæ.—Dr. James S. Cooley, of Glen Cove, L. I., writes us: It is a matter of no special importance, but your types make sad work with the recipe for the sativa cure, in a late issue of The Medical Record. I do not suppose anyone will attempt to put it up, but I intended to write it plain enough for any compositor. I give you a copy below, which you will see, by comparing with the formula in The Record, is different in several respects.

Ext. Asiatic cannabis sativa	ʒ ij.
Ext. Asiatic halish sativa	ʒ iij.
Verbena hastata	ʒ ij.
Extract diosma	ʒ iij.
Pulv. cinchoni bark	ʒ ij.
Extract Cashgar leaves (blood root)	ʒ iij.
Inulin	ʒ j.

I have also the recipes for Le Grande's Arabian Catarrh Remedy, which is of two kinds, as follows:

Internal Remedy.

℞.	Extract Arabian calla root	ʒ jss.
	Comp. tinct. Arabian red lava flower	ʒ ij.
	Ferro citrate calcium	ʒ j.
	Bi-sulphate quineia	ʒ iv.
	Potassi iodide	ʒ j.
	Phospho salicylate	ʒ j.
	Glycerine	ʒ ij.
	Verium ferri q. s. ad	O j.
M.	One tablespoonful four times a day.	

External Remedy, for Nasal Douche.

℞.	Pulv. Arabian sea grass	ʒ j.
	Pulv. Arabian kanke root	ʒ v.
	Chlorate quinia	ʒ j.
	Acetate silica	ʒ iij.
	Soda sulph	ʒ j.
	Magnesia sulph	ʒ j.
	Glycerine	ʒ ij.
	Aqua picis q. s. ad	O j.
M.	A tablespoonful in a quart of lukewarm water and used with a douche.	

I have spelled the recipes as printed.

Simple Test for Wall-paper.—A simple and easily applied test for wall-papers has been devised by Mr. F. F. Grenstted. No apparatus is needed beyond an ordinary gas-jet, which is turned down to quite a pin-point, until the flame is wholly blue; when this has been done, a strip of the paper suspected to contain arsenic is cut one-sixteenth of an inch wide, and an inch or two long. Directly the edge of this paper is brought into contact with the outer edge of the gas-flame a gray coloration, due to arsenic, will be seen in the flame (test No. 1). The paper is burned a little, and the fumes that are given off will be found to have a strong, garlic-like odor, due to the vapor of arsenic acid (test No. 2). Take the paper

away from the flames and look at the charred end—the carbon will be colored a bronze-red; this is a copper reduced by the carbon (test No. 3); being now away from the flame in a fine state of division, the copper is slightly oxidized by the air, and on placing the charred end, a second time, not too far into the flame, the flame will now be colored green by copper (test No. 4). By this simple means it is possible to form an opinion, without apparatus and without leaving the room, as to whether any wall-paper contains arsenic, for copper arseniate is commonly used in preparing wall-papers. Tests one and two would be yielded by any paper containing arsenic in considerable quantities.—*British Medical Journal.*

A Ballad of Consistent Spelling.

There was once a young man who caught phthisis,
By being exposed to the brhisis;
So he—cold death to foil—
Took some cod-liver oil,
Which instantly brought on e-mhisis.

The Therapeutic Value of Mountain-climbing.—In the *New York Medical Journal* of February 26, 1887, Dr. L. Borkan, of Brooklyn, emphasizes anew the beneficial results obtainable from mountain-climbing. He says that pure air, such as is found in the mountains, is always the most active of disinfecting agents known. Thinly settled districts are much more healthful, other things being equal, than densely populated ones. Mountainous regions almost invariably belong to the former category. According to the author: "There are floating in the air numberless germs, many of them of a harmful nature, and it would seem possible that the injurious germs which, especially in large places, are received into the human organism, might be rendered innocuous by the oxygen of the air (and perhaps, also, by air-currents acting in a mechanical way), while in stagnant air—as, for example, in a badly ventilated apartment, where the exhalations from the lungs and skin are constantly accumulating—there is less disinfectant action because of the diminished quantity of oxygen. We seek to get rid as quickly as possible of the other excretory products, while, strangely enough, the same amount of zeal in disposing of the exhalations—that is, the excretions—of the lungs and skin is comparatively seldom exhibited." Dr. Borkan also maintains that, "the best inhalation apparatus, baths, and medicaments are of but temporary value if no compensation is made for the loss of vitality and of muscular tone, especially that of the heart and vessels; if the blood stasis in the glands and other organs does not yield to an increased flow of blood in the arteries and veins; if the thinned blood does not become thicker and more rich in albumen; if the accumulating carbonic acid is not expelled by a more plentiful supply of oxygen; if the fat deposited in the body is not more rapidly oxidized; and if the kidneys are not made to act more efficiently. But all these effects are produced, according to Jacobi, Loomis, Veit, Oertel, and other authorities, more certainly and more generally by mountain-climbing than in any other way whatever. After several weeks spent in mountain excursions, the condition of the patient is radically changed for the better. There is an elasticity of the mental processes in place of the former hebetude; will, thought, and impulse seem to move on wings; the formerly dull senses are sharpened; the formerly half-closed eyes sparkle, and the flabby cheeks become fuller and rosy; the formerly prominent abdomen is reduced to more seemly dimensions, notwithstanding that food and drink are taken with greater relish, and the chest is expanded." The author appears to have at various times acted in the capacity of medical *cicerone* to parties of men and women seeking to improve their health by excursions into the mountains. He says that, "in organizing parties for mountain-climbing, it is necessary to have everything arranged and to attend to certain preliminary details. Regulations should be established as to the gradual increase in the extent of the daily ascents, the periods for rest, the choice of food, the permission to drink, the regulation of time for stool, the protection of the feet, legs, and nates against chafing and the formation of blisters, the protection of the neck, and, finally, the selection of the mountain up which the ascent is to be made; these are all points which require careful consideration. The European mountains, where there is a better climate, and, as a rule, better paths than are to be found in the mountains of America, are to be preferred. An exception is, however, to be made in favor of the Adirondacks and some other mountains in the Eastern States, which might answer as places for exercise for American youths in search of health."

An International Congress of Cremation is to be held at Milan in September, 1887. Among the honorary presidents are Sir Henry Thompson, of London, and Professor Moleschott, of Rome.

The Relationship of Urea to Certain Morbid States.—Dr. Oliver says (*British Medical Journal*): "That urea originates from the decomposition of blood-corpuscles, and not from the disintegration of food. In the liver, the red blood-cells are known to undergo disintegration; the blood of the hepatic vein is much poorer in blood-corpuscles than that of the portal vein. It is out of the destruction of these hæmocytes that we get, on the one hand, the coloring matter of the bile; on the other, urea; and later on, from the bile, the coloring matter of the urine. In phthisis pulmonalis, where the liver is fatty or amyloid change has begun, the cells are no longer capable of performing their function, and the discharge of urea falls, in spite of the fact that there is a marked rise of temperature, and the patient consumes a fairly large quantity of animal food, wine, etc. If the tissues were the source of urea, then this is just the disease in which urea ought to be found in excess. But during the early stage urea is subnormal in amount; when, later on, it is in excess, it is found that the red blood-cells are rapidly becoming destroyed and the patient becomes anæmic. In lead-poisoning the urine is deficient in urea—a deficiency which, irrespective of sex, becomes marked when the anæmia has become pronounced, and still more marked when albuminuria is present. In malignant disease urea is in excess as long as the cachexia is forming—*i.e.*, during the disintegration of the blood-corpuscles. When the cachexia is developed the elimination becomes deficient. In the following morbid conditions, in which the blood shows distinct alterations in regard to the number of its corpuscles—viz., anæmia, pernicious anæmia, chlorosis, leucæmia, and myxœdema—the urine is generally deficient in urea, unless there is a rapid destruction of blood-cells going on, when the urea will be found in excess. In diabetes mellitus the urea is in excess, while in diabetes insipidus it is generally below the normal. In Bright's disease the urea is usually deficient. Dr. Oliver regards the liver as the organ chiefly concerned in the formation of urea. The tissues in their oxidation or disintegration contribute but little, if any. Food is a source, but not to the extent hitherto believed. During the process of starvation the daily discharge of urea is not much below the normal—a circumstance explained not so much by the disintegration and disappearance of tissue as by the fact that the tissues still form blood-cells, from the dissolution of which comes the urea. In the early stages of fevers, before the temperature has risen, the urine is found to contain an excess of urea, due to the sudden engulfment and destruction of myriads of blood-corpuscles in the liver. As a proof that the hæmocytes are the source of urea, the author takes any case of anæmia or cachexia; and, unless these changes are in the course of formation, it is found that the daily discharge of urea is diminished."

A Congress of Greek Physicians was held in Athens, on April 3d and 4th, on the occasion of the semi-centennial of the founding of the Medical Society of Athens.

Original Articles.

CONCERNING THE INFLUENCE OF SMALL QUANTITIES OF SODIUM, CALCIUM, AND POTASSIUM SALTS UPON THE HEART AND SKELETAL MUSCLES OF THE TORTOISE.

BY SYDNEY RINGER, M.D., F.R.S.,

PROFESSOR OF MEDICINE IN UNIVERSITY COLLEGE, LONDON;

AND

DUDLEY BUXTON, M.D., B.S.,

ANÆSTHETIST IN UNIVERSITY COLLEGE HOSPITAL.

IN the present paper we record experiments made with the heart and skeletal muscles of the tortoise. The experiments and the results arrived at, which we shall detail with regard to the ventricle of the tortoise, are similar to others already published dealing with the ventricle of the frog (*Rana temporaria*) and that of the eel (*Anguilla muræna*).

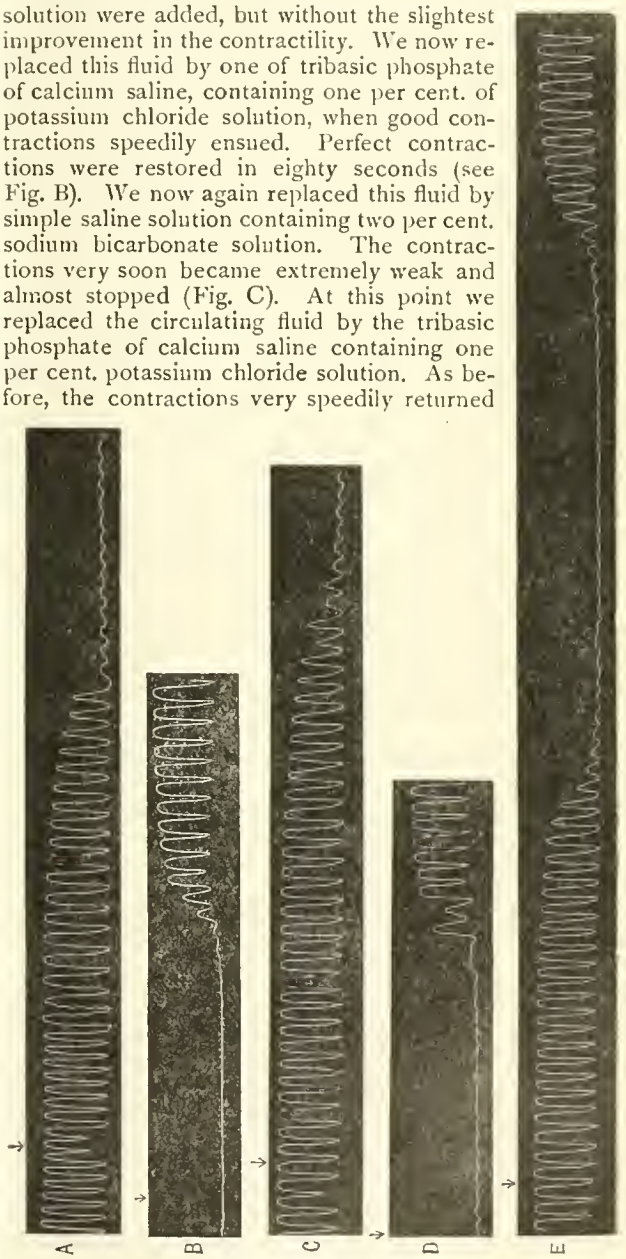
In our investigations on the tortoise's ventricle we employed a Roy's tonometer; we tied the heart in the auriculo-ventricular groove, and inserted the perfusion-cannula through the sinus into the ventricle. The aorta was also secured with a ligature. In our experiments we employed both the land-tortoise and the water-tortoise.

It is important to remember that the ventricle of the tortoise possesses coronary vessels, which, of course, assist in maintaining its nutrition, but this applies only to the outer portion of its thickness. The inner part of the tortoise's ventricle, like that of the eel and frog, is spongy, and is traversed by trabeculæ, and this, comprising the main thickness of the wall, is nourished by direct imbibition of the blood flowing through its cavity.

The experiments given below were made during the month of November, 1886; the temperature of the laboratory was, however, practically the same for all the experiments. The solutions employed were .6% saline solution; .6% saline solution saturated with tribasic calcium phosphate siphoned off after settling; also, one per cent. solutions of sodium bicarbonate and potassium chloride.

Commencing our experiments by circulating simple saline solution through the ventricle, we found, as with the frog and eel so with the tortoise, that such a fluid is incapable of maintaining contractility. The addition of one cubic centimetre of sodium bicarbonate solution, or of potassium chloride solution, or a combination of these solutions, in each hundred did not enable the saline solution to sustain contractility. When substitution of saline solution by tribasic phosphate of lime saline is effected, the contractility is speedily restored. This solution, however, not only restores good contractions, but also broadens the trace, rounds its top, and delays diastolic dilatation, and so brings about fusion of the beats. The addition of one or two per cent. of potassium chloride solution, however, quite obviates these "lime effects," so that we find tribasic phosphate of calcium saline with one per cent. of potassium chloride solution constitutes an excellent circulating fluid which is able to sustain natural contractions.

On November 18th we commenced an experiment by circulating phosphate of lime saline with one per cent. potassium chloride solution. This we replaced by simple saline solution, and in two minutes the trace became very weak, the record only giving a slight wavy line (see Fig. A). Two cubic centimetres of sodium bicarbonate solution to the hundred cubic centimetres of saline solution were added, but without the slightest improvement in the contractility. We now replaced this fluid by one of tribasic phosphate of calcium saline, containing one per cent. of potassium chloride solution, when good contractions speedily ensued. Perfect contractions were restored in eighty seconds (see Fig. B). We now again replaced this fluid by simple saline solution containing two per cent. sodium bicarbonate solution. The contractions very soon became extremely weak and almost stopped (Fig. C). At this point we replaced the circulating fluid by the tribasic phosphate of calcium saline containing one per cent. potassium chloride solution. As before, the contractions very speedily returned



EXPLANATION OF FIGURES.

A, Shows the effect of substitution of six per cent. saline solution for phosphate of lime solution (saline solution saturated with tribasic phosphate of lime) containing one per cent. of a one per cent. solution of potassium chloride. The arrow indicates the point at which the phosphate of calcium replaced the saline solution.

B, Shows the effect of replacing saline solution containing two per cent. of bicarbonate of sodium ($NaHCO_3$) one per cent. solution. The arrow indicates the point at which the change was affected in this and in succeeding changes.

C, Shows the effect of replacing phosphate of lime saline solution containing one per cent. of potassium chloride solution by saline solution containing two per cent. of a one per cent. solution of sodium bicarbonate.

D, Shows the effect of replacing saline with two per cent. of a one per cent. solution of bicarbonate of sodium by phosphate of calcium solution containing one per cent. of a one per cent. solution of potassium chloride.

E, Shows the effect of replacing the phosphate of lime saline containing one per cent. of a one per cent. solution of potassium chloride solution by saline solution containing one per cent. of a one per cent. potassium chloride solution, and the effect of again returning to phosphate of lime saline with one per cent. of a one per cent. potassium chloride solution.

(Fig. D), recovering their previous amplitude. The next change was the substituting for the circulating fluid one

consisting of simple saline containing one per cent. potassium chloride solution. The contractions immediately grew weaker, and eventually all but ceased, but were again restored to their normal size by a replacement of the saline and potassium chloride by the tribasic phosphate of calcium saline with one per cent. potassium chloride solution (Fig. E).

Subsequently we tested the effect of tribasic phosphate of calcium saline solution, and found that although it produced good contractions it broadened the trace, rounded its top, and delayed diastolic dilatation and induced fusion of the beats. All these effects were removed by adding one per cent. of potassium chloride solution, a normal beat resulting. After an hour and a half, and in spite of all the changes above narrated, the contractions of the ventricle were found to be only one-quarter weaker than at the commencement of the experiment.

We also tested the behavior of the auricle of the tortoise's heart, and found that it also contracted weakly when fed with saline solution, and that when its contractions had almost ceased—owing to the effect of the saline solution—the addition of a lime salt was able to restore and sustain a normal contraction.

Now, study of the tracings not only shows the marked effect produced by the lime salt in promoting contraction, and the contrary effect when lime is withheld, but it reveals the fact that these effects are produced with great rapidity. For instance, when phosphate of lime was withheld the contractions very rapidly weakened, and in from ninety to one hundred seconds had almost ceased. On restoring lime to the circulating fluid, a restitution of normal contractions took place in about the same time. Of even this short space of time, a part—although, of course, a very small part—must be consumed by the passage of the fluid along the afferent tube. The question then arises, How do lime salts exercise so rapid an influence upon the ventricle as to bring about such very material alteration in its contractions? It would appear that the circulating medium might affect the muscular tissue by coming to it through the coronary vessels, and so obtaining the most intimate action through the capillary circulation; but, on the other hand, the circulating fluid might come into close contact with the muscular tissue by filtration, diffusion, and osmosis through the endocardium. To investigate this question we performed an experiment similar to the above, but taking care to tie the ligature so as to include the heart-substance at the base of the aorta, and so effectually to exclude the possibility of coronary circulation. We found, however, that even when the cannula was passed well into the heart, and a ligature secured tightly in the auriculo-ventricular groove, that we obtained the same effects from circulating lime salts, and as rapidly as when the coronary circulation was presumably intact. It would then appear that the circulating fluid is able to rapidly permeate the endothelium covering the trabeculæ of the tortoise's ventricle, and so conveys to, or withdraws from, the muscular protoplasm lime and potash salts according to the composition of the circulating fluid. But the extreme rapidity with which lime and potash salts bring about changes in the characters of the contraction of the tortoise's ventricle may seem to preclude or throw doubt upon the explanation that these salts act by filtration and diffusion through the endocardium.

It might be suggested that these salts act through the nervous system, but their influence upon the heart is clearly of a different character from inhibition or its withdrawal, since a heart which has been inhibited by the vagus will still contract fully when excited by a stimulus applied to the muscular substance itself; but a heart arrested by a circulating fluid devoid of lime will not contract when plied by the most powerful direct stimulation. If it should turn out that calcium and potassium salts do exert their influence through the nervous system, it must be concluded that lime salts act upon the nervous mechanism of contraction, potassium salts upon that of dilatation.

Whether these salts influence the muscle directly by filtration, or indirectly through the nerves, they can exert their influence only in a very slight degree unless they act under considerable pressure, as when their solution is forced into the ventricular cavity and distends it by considerable lateral pressure. This question of the influence of pressure is illustrated in the following experiment: If the whole heart of a tortoise is placed in a fluid, and fixed by passing a pin through the aorta into a loaded cork, while the ventricle is suspended by means of a thread passed round the frenum at its apex, and secured to the lever of a recording apparatus suspended by a thin strand of india rubber, the movements of the lever show that the effects of the solutions of various salts are quite different from those which follow the circulation of similar solutions under pressure through the cavities of the heart.

The heart was treated as above and placed in 300 c.c. simple saline solution, and its contractions grew weaker, but only gradually. At the end of an hour and a half the contractions were reduced to about one-half their initial size. We then drew off the fluid and replaced it by an equal amount of saline solution saturated with tribasic phosphate of calcium. No improvement, however, in the size of the contraction took place; on the contrary, the contractions still grew weaker. We added 3 c.c. of the potassium chloride solution after half an hour's time, but without any perceptible change occurring in the contractions. The further addition of 3 c.c. bicarbonate of sodium solution did not check the steady weakening. So we see that, employed in this way, simple saline solution only very gradually weakens the heart's contractions, and that neither phosphate of lime, chloride of potassium, nor bicarbonate of sodium can remove this weakening or prevent the gradual increase of the weakness. When at the close of the above experiment the heart had almost stopped, we circulated through it tribasic phosphate of lime saline with one per cent. chloride of potassium solution, but failed to improve its contractions. The failure to obtain effects from potash and lime salts when the heart is suspended in their solutions might, we surmised, arise from a possible difference between the power of absorption, etc., of the endocardium, on the one hand, and the pericardium, on the other. To test this we repeated the above experiment with a heart divided longitudinally from apex to base, and from side to side. In this way the cavity of the heart was brought into direct contact with the solution in which the heart was immersed. We tested one-half of the ventricle. The initial contractions were very strong, but gradually decreased in force, and at the end of fifty minutes were decidedly weakened. At this time we replaced the saline solution by tribasic phosphate of lime saline in which was 1 c.c. chloride of potassium solution in the hundred, and an immediate improvement occurred, the contractions recovering completely. We then returned to saline solution, and at once the contractions weakened, and in ten minutes were reduced to half their initial size. We now replaced this fluid by tribasic phosphate of calcium saline containing two per cent. potassium chloride solution, with the effect of increasing the size of the contractions by one-fourth. We did not, however, fully restore the contraction to its original size. From these experiments we see that either through the endocardium or the cut surface of the muscle the salts in solution exercise slightly more influence than when they act mainly upon the pericardium, only so much solution acting upon the endocardium as could find its way inside the ventricle through the cut sinus and aorta. And, further, the effect upon the divided ventricle was much less than on the entire ventricle, provided the fluid in the last case is allowed to perfuse under pressure through a cannula; so that we conclude that to obtain the lime and potash effects these salts must be circulated through the heart under pressure, a view which tells in favor of the theory that the salts act directly upon the muscular substance by actual filtration through the endocardium.

In a previous communication[1] we have shown that saline solution, lime and potassium salts in solution, do not affect skeletal muscles in the same way in which they influence the substance of the heart.

When placed in saline solution the frog's sartorius very slowly loses its contractility; the contractions, although weakened, do not cease for an hour or an hour and a half alter immersion. When the contractions have grown weak, if the saline solution is changed for one containing a lime salt, either no improvement in the contractions takes place or only a very slight one which is also only transient. The addition of the lime salt does not prolong the contraction nor does it delay relaxation. Since the publication of the above facts concerning the sartorius muscle we have extended our observations; we have employed the gastrocnemius muscle, and we find that it gives precisely the same results when placed in solutions of various composition as the sartorius.

This well-substantiated difference between skeletal and heart-muscle is in some measure explained, we believe, by some of the experiments recorded in this paper.

If the heart of the frog or of the tortoise is suspended in saline solution, and the contractions are recorded without circulating a fluid through the cavities, the ventricle behaves just like a skeletal muscle, and the contractions very slowly become weak—in the case of the tortoise's heart persisting for many hours. The addition of a lime salt does not improve the contractions, nor does it alter their character, *e.g.*, as by delaying dilatation, etc. If the tortoise's ventricle is divided so that its cavity is directly exposed to the action of the fluid in which it is suspended, much the same happens, save that the addition of a lime salt to the fluid will slightly improve the contractions, which had been weakened by saline solution. In fact, it appears that the rapid effects of saline solution and the characteristic effects of the solutions of lime salts or potash salts are only elicited when the solutions circulate through the ventricle, and are induced by lateral pressure to traverse the delicate endothelium, and so infiltrate the spongy muscular tissue itself.

And thus we conclude that the differences between the behavior of skeletal and cardiac muscle probably depends upon the way in which the testing fluid is applied; for if either is suspended in the fluid their behavior corresponds, and lime cannot in either case restore weakened or arrested contractility.

We next investigated the behavior of skeletal muscle when the test fluids were circulated through the muscle by traversing its capillaries. And we found that the same results were arrived at for cardiac and skeletal muscle, provided the test fluids were circulated in the one case through the heart-cavities, and in the other through the capillaries of the muscle.

We inserted a cannula into the descending aorta of a tortoise, and, having tied it in, introduced the test fluid while we secured the outflow by another cannula tied in the vein. The contractility was tested by faradization, a single Daniell's element being used and the coil kept constantly at 6. It took a considerable time to wash out the blood from the vessels; indeed, the fluid which flowed from the veins remained tinged with blood for an hour and twenty minutes, and so long as this was the case the contractility of the muscles remained unimpaired. After another ten minutes the outflow was quite colorless, and the contractility was much lessened. The coil was run up to 4 without increasing the amount of the contraction. In an hour and forty minutes the muscles had almost lost their contractility; we then caused saline solution saturated with tribasic phosphate of lime to traverse the vessels, and in four minutes found contractility much improved. In ten minutes this improvement was very marked, and we again returned to a circulating fluid of simple saline solution. In four minutes after this, contractility had become greatly impaired, but on resuming the supply of calcium phosphate saline the contractility returned in two minutes. We then returned to saline solution, and in three minutes contractility disappeared; so we again supplied the phosphate of calcium saline, and the contractility greatly improved in eight minutes. We repeated these changes of saline to phosphate of calcium saline, and back again to saline, on three more occasions, and each time the saline medium checked contractility, while a return to phosphate of calcium saline solution always produced excellent contractions. These observations were verified by subsequent experiments, the same results coming out.

We also found, on further experiments, that when 1 c.c. of a ten per cent. solution of calcium chloride was added to the 100 c.c. of calcium phosphate saline solution, the restoration of contractility of the muscle was more rapid and more complete.

We see from the above facts that the power a lime salt possesses of restoring the contractility of skeletal muscles, which had ceased, by the circulation of saline solution through the vessels, depends upon the way in which the lime salt is applied to the muscle. If it is conveyed through its capillary vessels, a mode quite analogous to circulating a fluid through the cavities of the heart, the lime salt speedily restores contractility when that has been suspended by a saline solution circulation. We see, also, when saline solution is circulated through a muscle in this way, that the loss of that muscle's contractility is very rapid, and is as speedy as is the suspension of contractility in the heart-muscle when saline circulates through the heart-cavities. Therefore it appears that lime salts exert the same influence on the contractility of skeletal as on cardiac muscle.

There is yet another point which claims our attention. In our previous experiments, recorded in the *Journal of Physiology* for 1887, we found that if the sartorius muscle of the frog is immersed in saline solution it slowly loses its contractility.

Contractions, although weak, may persist for an hour and a half; but after this time has elapsed even the addition of phosphate of lime or chloride of lime in large quantities fails to restore or improve contractility. This inability to restore contractions cannot, however, be due to non-absorption of lime, since the lime does exercise a decided effect in another direction, namely, by removing contraction remainder. We think that the reason why the lime salts do not under these circumstances produce improvement in the contraction is, that the rate with which the contractility declines is very slow, so that the muscle during this time is permanently damaged, and so is incapable of resuscitation. This view seems to be rendered probable by the following facts: If the heart be fed with saline and kept non-contractile for an hour, the addition of lime salts fails to restore contractility. And, again, it has been pointed out above that the tortoise's heart, if suspended in saline until all contractility ceases, will not regain its contractility even when phosphate of calcium saline is circulated through it.

Reviewing the results of the experiments above described, we think the following facts and inferences deserve especial attention: Saline solution when circulated through muscle in such a way as rapidly to come into intimate contact with the muscular protoplasm induces lessening or loss of contractility, and does so with great rapidity. This action is exerted alike upon cardiac and skeletal muscles.

Lime and potash salts, also, when brought into like intimate relation with muscular protoplasm possess a power of affecting muscular contractility. Lime salts speedily restore contractions when such have been stopped by saline solution, and this they do alike to cardiac and skeletal muscles.

These facts, as we have shown, hold good for the heart-muscle of the frog, the eel, and the tortoise, and for the skeletal muscles of the tortoise, and probably have a very much wider application.

THE BEST TESTS FOR ALBUMIN, AND SOME POINTS RELATIVE TO URINARY EXAMINATIONS.[1]

By HENRY B. MILLARD, M.D., A.M., Etc.,
NEW YORK.

That neither the presence of albumin in the urine nor its absence of itself demonstrates disease or healthfulness of the kidneys, we all know. In an advanced state of cirrhosis, albumin may be temporarily absent, while it may exist in inconsequent functional derangements or as the result of simple glomerulitis without any diffuse nephritis. I think, nevertheless, the existence or non-existence, if either of these conditions be persistent, a circumstance of greater weight, in the majority of cases, than any other except such conditions as the microscope shows, in aiding us to determine whether or not the case be one of nephritis.

The general practitioner has few examinations to make on which depend more grave issues than the apparently simple one of testing for albumin. Yet how imperfectly and inaccurately this examination is often made, and how uncertain its conclusions! There is no danger of too much being written upon this theme, homely even if it seem in comparison with brilliant novelties or apparently more intricate subjects in medical practice, nor of the matter being over-studied. With a large experience in these examinations, I sometimes find it difficult, until I have examined several specimens, to decide whether urine contains serum-albumin. I do not propose to consider here the chemistry of the protein bodies met with in the urine, but to refer only to the various substances that may be mistaken for albumin and the readiest way of discriminating the latter. The only tests I think it essential to consider here are:

Nitric acid—Dr. Roberts' modification of the nitric-acid test by the sulphate of magnesia, and which for convenience I will speak of as the *nitric-magnesian test*—and *heat.*

Among the most difficult things to distinguish from albumin are mucin and certain elements always found in urine where there is leucorrhœa, even mild cystitis, cervico-metritis, gleet, etc. Such urine is commonly thought to contain mucus, but according to Méhu[2] mucus is seldom, if ever, found in the urine. Epithelia from the various regions, with their detritus, some partially and some wholly disintegrated or dissolved, leucocytes, pus-corpuscles, pyin, and, where there is much inflammation, the serum of the liquor puris, are contained in the urine where there is cystitis, vaginitis, etc. The broken-down and dissolved epithelia contain many protein elements, and these, with the other substances I have just mentioned, give many of the reactions of albumin. According to Méhu, the cloudy sediment which occurs so often in the urine does not contain vesical mucus, as this is not a special secretion, and the term "muco-pus," etc., should disappear. Mucin, however, is definite and easy to characterize; it is invisible, viscous, making the urine foamy, being precipitated by acetic acid, and does not redissolve in an excess of it.

"The sticky substance in chronic cystitis is formed from the decomposition of the leucocytes, etc., by the urea and the carbonate of ammonia." Urines such as these produce a slight cloudiness, due to the precipitation of anatomical elements held in solution, being more abundant in proportion as these elements have been retained a long time in the urine, and as the latter is less dense and less acid, becoming more ammoniacal. Heat, aided by weak acetic acid, produces still more cloudiness, but no albuminous flakes. Tanret's test gives a cloudiness and sometimes a well-marked turbidity without albumin, albuminose, or mucin being present. It is in this very common class of cases that the observer is too inclined to conclude that the urine is "loaded with peptones" (Méhu, *loc. cit.*). Although many protein bodies exist in the urine the existence of peptones is much less common than is usually supposed. The variety of proteids in the blood and urine is very great, and between the serum-albumin and the peptone of the urine there are numerous protein substances, ill-defined; these are nearly all precipitated by Tanret's test, alcohol or heat causing them to disappear. I have made many experiments relative to this subject, some of them showing the liberation, from beef powders which had been boiled, of protein substances, but no albumin. A part of these experiments are given in an article in The Medical Record of April 4, 1885.

The substances, then, most likely to be mistaken for serum-albumin are, first, the various protein bodies, peptones, and the alkaloids; these, when Tanret's test has been employed, easily disappear on the application of heat or alcohol; second, mucin, pyin, the various dissolved albuminous substances found in inflammatory states of various portions of the genito-urinary tract, and last, the glutinous substance formed by decomposition. With these two last, nitric acid, which is so satisfactory in other respects, becomes uncertain. Nevertheless, an explanation of the doubtful reaction is always possible, and this brings me to the consideration of two important points:

First, *the careful preparation of the urine for examination*, and second, *the best tests.* In many cases practitioners do not take requisite pains to enable them to determine with certainty whether or not renal albuminuria exists, sometimes from not realizing the importance of certain details, and sometimes from lack of time or patience. In cases of slight albuminuria, as where, for instance, there is not more than one one-hundredth of one per cent. of albumin, and in cases where pus, mucin, and the various substances I have described occur, it is sometimes a matter of great difficulty to determine whether or not there is renal albuminuria. I have several times been called in consultation in cases where renal symptoms apparently existed, as anasarca, etc., which symptoms, with the supposed existence of albumin in the urine, had led to the diagnosis of Bright's disease, but where the kidneys were perfectly healthy, the appearance of albumin in some cases being produced by the reaction of the urates with nitric acid, in others, by various other causes. The necessary precautions, tests, etc., are, however, easily practicable, though time must not be too much economized. I think physicians should take more pains to impress upon patients the necessity of observing certain details in sending the urine. I have known it sent in hair-oil bottles, sometimes decomposed from being collected from vessels not perfectly clean, and sometimes, from standing too long, perhaps, full of bacteria; and in examining the urine of the male I have found epithelia from the vagina, showing a communality in a certain article of this world's goods quite in accordance with socialistic doctrines, but inconvenient in urinary examinations. I have found it necessary to have a card like this printed:

IMPORTANT DIRECTIONS FOR SENDING SPECIMENS OF URINE.

The vessel in which urine is passed must be perfectly clean.
A new bottle should be used.
Send a ounce bottle urine passed.

Put your name on wrapper, and date of day on which urine is passed.

Patients should be made to understand that the examination of the urine for albumin is not always a simple affair, and cannot be properly done without entailing upon them some expense. A gentleman from Chicago who lately consulted me told me that a physician of that city, of recognized ability and a professor in one of the best medical colleges there, made him a charge of only one dollar for each consultation and urinary examination. Physicians in large cities, if their time be much

[1] Read before the Section on Theory and Practice of Medicine of the New York Academy of Medicine, April 19, 1887.
[2] De la non existence du mucus de l'urine, Bull. gén. de Thérapeutique, Août 1886.

occupied, must do their patients scant justice at such rates, unless they are so fortunate as not to be dependent on their professional fees for a livelihood. I may say that in this instance an entirely inaccurate diagnosis had been made. When I require the urine of women for examination, I direct *thorough* syringing of the vagina to be resorted to before the urine is passed; traces of albumin can be found in the urine of every woman who suffers much from leucorrhœa or cervicometritis. Aside from the examination for albumin, it is no small comfort, in case a microscopic examination be made, to find the specimen free from vaginal or vesical epithelia, etc. As a rule, the urine requires to be clarified; it is the exception when, even after standing for a considerable time, it is so clear that some of the elements, particularly mucin, will not be afloat in it, sometimes greatly embarrassing the work of testing. Unless very turbid from other causes than the urates, which disappear on warming the urine, I think filtration through a double thickness of Swedish filtering-paper will render it sufficiently clear. I find that with my own test (phenic and acetic acid and potash) urine that has been passed through the gray French filtering-paper gives a decided albuminous reaction, due probably to the presence of a minute quantity of vegetable albumin, and if with this test, it may be with others. When, however, the urine cannot be cleared by simple filtration, it may be boiled with a fourth part of liquor potassæ and then filtered. There are other methods, as with the magnesian fluid; but the fewer recommended in this paper the better, and it is rare that one of the first two does not prove sufficient. Without clarification, clean tubes, and a good light, the urine cannot be properly tested for albumin, or the fine and sometimes almost invisible sharp line seen, or almost imperceptible cloudiness from heat or Tanret's test recognized, which we expect to find when the urine contains only one-fiftieth or one one-hundreth of one per cent. of albumin.

The Best Tests.—I mean by these such as combine the merits of accuracy and facility of employment by the general practitioner. I will first consider the

Nitric-acid test.—The Clinical Society of London last July reported that it found this, all things considered, the best test, that is, the most reliable and delicate, and with proper precautions it is, in many cases, highly satisfactory. To employ this another precaution besides clarification is often necessary; however clear the urine, if urates exist in excess, they form with this reagent a turbid white zone above and in contact with it; this is not usually very dense in appearance, the part next the acid being, as a rule, most dense, the upper portion less so; sometimes, indeed, when with an excess of urates albumin is present, this latter will be seen as a sharp line below the zone produced by the urates, but the discrimination is not always easy. And permit me here to say that if, in referring to methods of using reagents, etc., I state some facts which should be familiar to every tyro in medical practice, it is not because I impugn mentally the high intelligence of the audience I have the honor of addressing, but because these facts form a natural and indispensable part of the context. When there is reason to suspect the existence of an excess of urates these may be dissolved before testing by letting the test-tube stand in hot water, not boiling, as this coagulates albumin, but having a temperature somewhat under 140° F., albumin coagulating at and above this figure. There is now no danger of this zone being formed, and a drachm or so of the acid being placed at the bottom of the tube, which is better for having a diameter of as much as three-fourths of an inch, the urine should be allowed to trickle slowly down upon it. If much albumin be present, it is quickly coagulated by the contact, and a white, lardaceous layer is at once formed. We will suppose that all the directions I have given have been followed, the test-tube is held before a clear, bright light, a book or some dark object is held before the layer of acid, but no sharp line appears, nor white layer nor cloud of any kind. We must by no means conclude that albumin is not there, but allow the urine to stand five, or even ten or fifteen, minutes; then, sometimes, we shall find a thin, clear, sharp line visible only upon careful scrutiny, and perhaps underneath it a colored zone produced variously by uric acid, biliary acids, iodine should the patient be taking iodide of potassium, etc., and above the albuminous ring, sometimes half way between it and the surface of the urine, an irregular ring of less density, probably mucin. If the urine be allowed to cool we may find four distinct zones; first, the orange-colored one, then one albuminous, the next formed by the urates, the upper one mucin. Dr. (now Sir William) Roberts says the mucin zone can be recognized by twirling the test-tube, when it will become diffused, while the albuminous layer will not. "Traces of mucin in a state of solution," says this author, "seem to be present in all urines, healthy and morbid, and this occasions more frequent embarrassment than any other substance." Nevertheless, nitric acid is troublesome, as giving a reaction when mucin or the elements in question are present. Still, according to Roberts, it is easily distinguished from albumin by being precipitated by weak, but not by strong, nitric acid and by forming a zone at some distance *above* the acid. When, however, mucin and the substances which pass for it are present in abundance, the discrimination by nitric acid is by no means simple. This reagent has the merit of not precipitating peptones or protein bodies. It produces a precipitate when resinous oils, as copaiba, cubebs, etc., are being taken, but this readily disappears on adding alcohol.

The nitric-magnesian test, as I shall term it for the sake of brevity, is a modification by Dr. Roberts of the test by pure nitric acid, and is described in an article by him in the *Medical Chronicle*, October, 1884. It is prepared by mixing one part of pure nitric acid with five parts of a saturated solution of the sulphate of magnesia, and filtering. The principal advantages claimed for it by Dr. Roberts are that it does not stain nor soil the fingers, that it does not show a coloration with iodine, and, most important of all, that it is a more delicate test than pure nitric acid. It is used the same way as the latter, a drachm being poured into the bottom of the test-tube, holding this nearly horizontal so that the two liquids do not commingle, since if they do the mucin and albumin are precipitated together, but otherwise are precipitated at different points.

I have used this reagent with chemically pure blood-albumin, made for me by Merck, of Darmstadt, and with a large number of specimens of urine, acid, alkaline, containing mucin, pus, the *débris* and dissolved elements found in inflammatory conditions of the vagina, bladder, etc., first, of course, freeing as thoroughly as possible the urine from these substances, and do not, from my own experience at least, hesitate to pronounce it, as regards delicacy, accuracy, and facility of employment, the most satisfactory test I have yet used. I have been able to discover by it albumin in the urine of chronic interstitial nephritis when no other test but Tanret's, or the equally sensitive one introduced by me of phenic and acetic acid and potash, would show it, and in the clarified urine of the male where the urine was remarkably clear and there was no inflammation, when it was not shown by nitric acid. In an extensive series of experiments made by me to determine the delicacy of certain tests, many of which were published in The Medical Record, in 1885, I found that nitric acid would not show more than one part of albumin in 100,000, that is, 0.163 grain to the litre, and I find that the nitric-magnesian test will show a smaller proportion.

It is not of much importance, everything else considered, if the amount of albumin do not exceed one part in 10,000, that is, one one-hundredth of one per cent. (equal to 1.63 grain to the litre). If urine containing about one-tenth of one per cent. of albumin be diluted

with distilled water, so that it will contain, say, one one-hundredth of one per cent., the nitric-magnesian test would usually be found to form a layer not more than one-half as thick as that produced by nitric acid, but much more compact and dense. Now, the former test possesses this very great advantage: that it condenses more thoroughly the albumin than does the nitric acid. It often happens that the zone produced by nitric acid will be light and fluffy, mucin or the substance I have so often referred to being directly in contact with it in considerable quantity, while that produced by the nitric acid and magnesian test would be condensed, compact, lardaceous, and clearly and sharply defined, the precipitate produced by the obnoxious elements being distinctly separated from it. This advantage I find in nearly every instance; a double advantage, as it not only shows clearly the presence of albumin, but makes it possible to determine with sufficient approximation the percentage of albumin contained in the urine. If every precaution be taken, Hofmann and Ultzmann's rule—that of a sharp, clear layer of albumin every three millimetres (about one-tenth of an inch), in thickness, indicates one-tenth of one per cent. of albumin—is sufficiently exact for clinical purposes. I have repeatedly verified the excellence and convenience of this rule; the nitric acid, however, often condenses the albumin so imperfectly that an albuminous zone, which from its imperfect concentration has apparently a thickness of two or three lines, does not really represent more than *one* line. The nitric-magnesian fluid produces such a compact layer that it can be taken with more confidence as a basis for the estimate of the quantity of albumin. In regard once more to the delicacy of this test, I have found it to show the presence of albumin after diluting it to a point where nitric acid ceased to show it, and have occasionally found it to show albumin when even Tanret's test did not. From my experiments I believe it to be easily a third more sensitive than nitric acid; that is, if this last test would show one part in 100,000, the test in question would show one part in 150,000. I must not, however, omit to state that this test cannot be used with urine that has been clarified with liquor potassæ, as a dense precipitate is at once formed, owing to chemical decomposition. The urine can, however, be sufficiently cleared by thorough filtration.

Other experimenters may find some, though I think not many, objections to this test that I have not. Yet who is there that has not, in a long medical experience, seen most promising, nay, apparently unassailable discoveries, disclose vulnerable points to the uncompromising test of continued experience?

Happy is he who does not in time find the value of his discoveries in our benign art vanish like the actors in the comedy of the "Tempest," "melted into air, into thin air," leaving "not a rack behind."

Heat, although somewhat more sensitive than nitric acid, I regard as one of the most cumbrous of the important tests. It shows phosphates, which are, of course, easily dissolved by acids; but if albumin exist only in minute quantity, this is liable to be so diffused by the addition of anything as to render it invisible. Then if the urine be too acid or too alkaline, it must be made less so, and it is sometimes very troublesome to add exactly the proper quantity of acid or alkali. There is also this very great disadvantage, that when the necessity exists for adding acetic acid, even if the urine have been thoroughly clarified, this acid produces a reaction due to the precipitation of anatomical elements in solution when the urine contains mucin, vaginal, or other epithelia, etc. The turbidity, though often slight, is sometimes very considerable, in either case it being impossible to employ heat with entire, if with any, satisfaction. Without any of the troublesome anatomical elements I have mentioned being present, acetic acid may produce turbidity with peptones or other protein bodies. I have found this to be the case with numerous artificial peptones, and with urines which gave the reaction of peptones with picric acid; the cloudiness thus produced disappearing by heat. Citric acid is preferable as an acidifying agent, since it does not give reactions with peptone, though it does with mucin, dissolved epithelia, etc. Dr. Roberts claims that heat can be made to show one part of albumin in two hundred and fifty thousand parts of urine, but I have not been able to recognize, after much experimentation, that it shows more than one part in somewhat more than one hundred thousand. I will sum up with reference to this test by saying that, though it is often a sensitive and excellent one, there are circumstances which sometimes render it unavailable, and at best it requires more work and precautions than the nitric-acid or nitric-magnesian test.

There have appeared within a year or two several articles in medical journals on what might be termed *ready methods of discovering casts*. How with the greatest facility to find casts as well as renal and pelvic epithelia, and how to find them at all, if they exist in very limited numbers, like Virgil's shipwrecked mariners,

> . . . "rari natantes in gurgite vasto,"

is certainly a matter worthy of consideration. If casts and renal epithelia be numerous, the problem solves itself; but there are many cases, especially of cirrhotic kidney, where the specific gravity of the urine is low, in which casts and renal epithelia will sometimes be temporarily absent, and when present, exist in such small numbers as to require much time and patience to determine whether they exist or not. These bodies will be often held in suspension in the light cloud of mucin which is formed in nearly all healthy, or comparatively healthy, urine, and are sometimes also prevented from forming a deposit by the bacteria which agitate the urine, so that it will often happen that in ten or twelve ounces of clear urine of low specific gravity it is very difficult to obtain much deposit. The plan I formerly pursued was, in cases where the sediment was scanty, as in polyuria where the specific gravity was very low, to add to the urine about ten per cent. of a one-half of one per cent. solution of chromic acid, this effectually preventing decomposition or the development of organic life; then mixing, after the urine had stood a considerable time, half a drachm or so from the bottom of the beaker with a little glycerine, and letting the watery portions evaporate, the glycerine would hold everything of a sedimentary nature. This method is satisfactory enough; but a great deal of time is required. I am indebted to Méhu for a method of obtaining with facility, *en masse*, all the organic and inorganic matter in the urine, and this process I have come to consider almost indispensable. I believe I can, however, best give his method by translating his own words.

"The acetic-acid solution of the iodide of mercury and potash (Tanret's test) facilitates in an eminent degree the reunion of urinary sediments, partly by combining the anatomical elements in suspension, and partly by rendering inert the bacteria and various vibriones which prevent a deposit of anatomical elements. In many healthy or pathological urines it happens, indeed, that the sediment remains in suspension, like a cloud, in the liquid mass. In order to examine this by the microscope it becomes necessary to withdraw a portion of this cloud by means of a pipette introduced into the floating mass, this mode of manipulation, however, presenting many inconveniences. To obviate this, it is only necessary to add to the urine two or three per cent. of its volume of the iodide of mercury and potash, to agitate the liquid, and to let it rest. The uric acid mingles with the sediment. When the urine is albuminous or loaded with peptones, only from a drop to a few drops need be added to produce the desired effect, too large a quantity of the reagent occasioning a too voluminous deposit" ("Sur la Recherche de l'Albuminose ou Peptone," *Annales de Maladies des Organes Génito-Urinaires*, May, 1884).

As there is "no royal road to learning," so there is

none to the discovery of casts and renal epithelia under certain circumstances; the method of Méhu is without objection, and concentrates in a short time into a small compass everything in the urine needing recognition. Still, even with the deposit thus concentrated, it is necessary in many cases to "put up" several drops, and to employ long, laborious, and patient research before being able to arrive at an assurance of the presence or absence of the suspected bodies.

THE PRACTICAL VALUE OF OUR PRESENT METHODS OF TREATING THE UPPER AIR-PASSAGES.[1]

By F. H. BOSWORTH, M.D.,
NEW YORK.

It is now thirty-three years since Garcia, of London, demonstrated the feasibility of examining the interior of the larynx during life, followed by Czermak, of Pesth, who, making practical adaptation of Garcia's teaching, presented to the medical profession a new method of treating disease, and thus inaugurated a new specialty. It seems eminently fitting that, at the present time, when our specialty occupies so large a share of public and professional attention, when new and important observations crowd one upon another so rapidly, and the results of treatment are so much more flattering in their success than ever before, we should pause for an instant (take an account of stock, as it were), to examine the by-technique which has built itself up around our practice, and put it to the test of experience, indorsing all that is good and rejecting that which is bad.

The early days of our specialty were days of invention, and so rapidly did the number of appliances and ingenious devices for treating diseases accumulate in our hands that the impression grew that we treated disease by machinery. Nor was this impression ill-founded, for so extensive and complicated has the mere mechanical features of our specialty become that the laryngologist's office has grown to be not unlike a machine-shop.

I long since began to ask myself the question, how much aid has all this machinery been in the successful treatment of disease? This is to largely be the subject of our discussion to-night.

The point of view which I take is, that when we knew little about the treatment of these diseases our machinery was very extensive. As our knowledge increased, the machinery rapidly diminished; and now that we finally obtain striking success in the management of the majority of the diseases of the upper air-passages, I think I may safely say that all the machinery necessary might be carried in a small hand-satchel.

In discussing special methods of topical applications, I will make a few remarks successively on the treatment of the larynx, lower pharynx, vault of the pharynx, and the nasal passages.

As regards topical applications to the larynx, in the early days of our specialty, brushes, sponges, probangs, syringes, sprays of various kinds, were made use of in the treatment of so-called chronic laryngitis, and their comparative merits were discussed with great seriousness. Whatever may have been their comparative value, a question of far greater importance is, did any of them ever do any good?

I think I am safe in saying that in the whole history of laryngology no case of so-called chronic laryngitis was ever cured by topical applications, whether made by brush, sponge, or spray. The more serious affections of the larynx, such as tumors, syphilis, cancer, tuberculosis, paralysis, etc., of course no one ever claimed to cure by topical agents.

I have already expressed my views with regard to chronic laryngitis, and will not repeat them here, but will content myself with simply saying that the condition called chronic laryngitis is merely symptomatic and secondary to disease of the nasal cavities in every case. The morbid condition is not an hyperæmia with hypersecretion, to be corrected by an astringent, but rather a perversion of the normal secretion of the part, due to the morbid lesion above.

Applications to the lower pharynx from time immemorial have been made by brushes, sponges, cotton pledgets, sprays, syringes, etc., for the purpose of relieving a supposed chronic pharyngitis. Various astringents have been applied with the idea of correcting hypersecretion. I have elsewhere tried to make plain the fact that the lower pharynx is in no sense a part of the air-tract, but is a part of the food-tract; is covered with hard pavement-epithelium with limited capacity for secretion; is rarely, if ever, involved in inflammatory process of the air-passages, and therefore local astringents, however applied, do not cure.

The vault of the pharynx, we have finally learned for the first time in Mackenzie's second volume on "Diseases of the Throat and Nose," is the seat of morbid changes which characterize what has been called in years past naso-pharyngeal catarrh. What these morbid changes are, however, neither Mackenzie nor any other writer has ever made clear to us, the truth being that there is no such disease as naso-pharyngeal catarrh in the sense of it being a catarrhal inflammation of the vault of the pharynx. This disease, which is supposed to consist essentially in an excessive secretion from the vault of the pharynx, due to a chronic inflammation of its lining membrane, is a myth. This excessive secretion is in reality diminished secretion. It is a normal secretion from a healthy membrane, but undergoing subsequent change as the result of disease in the part above. The indications for treatment are not astringents, but rather some method which reaches the cause or source of the disease which lies in the nasal cavities themselves. No local application by brush, sponge, or probang behind the palate to the vault of the pharynx, in the whole history of laryngology, ever cured or even mitigated the severity of this so-called naso-pharyngeal catarrh.

As regards such conditions in the vault of the pharynx as hypertrophy of the pharyngeal tonsil, acute or chronic inflammation, neoplasms, or other diseased conditions consisting in structural changes, no local agents are of any avail other than palliative, as the indications are clearly for surgical measures.

In the treatment of so-called nasal catarrh a vast amount of ingenuity has been exercised in devising methods of making topical applications to the whole membrane lining this cavity, and some extravagant claims have been made as to the superior success of certain measures above others, ignoring the question as to the amount of real benefit derived even if the applications do reach the whole cavity. We are confronted here at the outset with the question as to what is nasal catarrh, so called.

I again take the ground that the disease which has figured so extensively in our medical literature as nasal catarrh is not a hypersecretion, to be cured by the local application of astringents. Even if it were a hypersecretion, the whole list of astringents which are found in our pharmacopœia have been tried in vain. I have not time here to enter upon the discussion of this question of the true pathology of nasal catarrh, nor the right, as it is but a short time since I presented the subject to you in a paper read from this desk on "Deflections of the Nasal Septum." I took the ground then that essentially the symptoms of so-called nasal catarrh are due to those morbid conditions of the nasal mucous membrane which interfere with the great respiratory function of the nasal passages—namely, exosmosis of serum. And, furthermore, that the so-called catarrh of the pharynx, larynx, and trachea are merely secondary to this condition, and not diseases in themselves, being amenable only to

[1] Read before the New York Academy of Medicine, April 21, 1887.

treatment directed to the real seat of disease—viz., the nose. I say that douches and sprays have never yet cured cases of catarrhal inflammation in the upper air-passages. I do not mean by this to utterly condemn their use. They have their uses, undoubtedly. They are of very great assistance to us in the management of our cases, but if we depend alone upon the use of local applications, no matter what special astringent we use, or stimulant or alterative ; no matter how elaborate our pumps and thickly plated our air-receivers ; no matter how expensive and complicated our machinery, we will fail absolutely and utterly in giving that amount of relief which our patients are entitled to receive at our hands —namely, a complete and radical cure.

The nasal douche, first suggested by Weber, afterward appropriated by Thudichum, and improperly called Thudichum's douche, has occupied a prominent place among our therapeutical resources. Its advantages have been lauded, and its dangers have been insisted upon. Its advantages are that it is an excellent method of reaching the whole nasal cavity for cleansing and palliative purposes ; radical good, it does none. Its dangers are vastly overestimated. I have never seen bad effects from its use.

Inhalations at one time filled a prominent place in our therapeutic resources. They have deservedly fallen into disuse, as it is very questionable whether they were ever of any permanent service. Sprays have always deservedly occupied the most prominent place among our therapeutic resources. Various forms have been suggested, and various methods of producing sprays have been in use, and what shall we say of these devices? Simply this : Sprays have been of great help to us as cleansing, as palliative remedies, and nothing more. Is there any special virtue in any one form of apparatus, or in any one form of spray? Unquestionably not. We frequently see in the columns of our journals some new invention, or new device, or new suggestion regarding the spray-tube, air-pump, air-receiver, which it is claimed possesses certain specified advantages over all others. The validity of these claims I should call in question. Compressed air, as a force for generating sprays, has been supposed to possess superior advantages. The moral effect on the patient undoubtedly is often very great. Its advantages over simpler apparatus I regard as nothing. I hold in my hand here a simple hand-ball spray, which is sold in the drug-stores for one dollar and a half. I think I am justified in saying that the spray produced by this little apparatus is as efficacious as any produced by the most elaborate and most beautiful and most expensive air-pump and receiver that can be made. In former days we paid higher prices for spray-producers with a double bulb, one of those absurd devices which, after its first introduction, it took us years to rid ourselves of. A far more vigorous spray, as you see, is produced with a single bulb, which gives the full pressure which can be exerted by the fingers, the double-bulb spray being projected by the contractile force of a thin India-rubber ball.

The treatment, then, of catarrhal affections of the upper air-tract, from my point of view, consists in the treatment of the nasal passages. And this involves the restoration of these passages to a normal condition by the removal of obstructing bone and cartilage, reducing hypertrophied membrane, and correcting hyperæmia or other morbid conditions ; in other words, in the use of the snare, the saw, the knife, and the cautery. I shall speak of but one of these devices.

The cautery has figured very extensively for many years in our literature as a valuable method for reducing obstructing lesions in the nasal passages. Now, I think I am justified in claiming that the object to be accomplished by the use of the cautery is not the destruction of tissue. If you stop to think for a moment of what the anatomy of the nasal mucous membrane is, I think you will see the truth of my reasoning. The superficial layer of epithelium is superimposed upon a bed of connective tissue containing blood-vessels, nerves, and beneath that we have a large plexus of blood-vessels—the falsely called erectile tissue. In hypertrophy the thickening largely involves the connective-tissue structures which are found in the intra-venous spaces and above. The epithelial layer is not thickened. Now, it is idle to suppose that a superficial destruction of this membrane reduces hypertrophy. It would be not unlike lowering a house by taking off its roof. We certainly should destroy its usefulness as a dwelling. The essential condition in what we call hypertrophic rhinitis is chronic hyperæmia of the blood-vessels, with increased nutrition. A caustic applied on the superficial layer of the mucous membrane reduces the amount of blood-supply to the part, arrests hyperæmia, diminishes nutrition, and in this way restores healthy action.

This is accomplished in the following way : The mucous membrane in a state of hyperæmia is treated with a solution of cocaine, which, as I first pointed out three years ago, exercises a specific action in causing vigorous contraction of the unstriped muscular fibres found in the coats of the blood-vessels. The blood-vessels thus become emptied, and the membrane, rendered pale and anæmic, clings closely to the turbinated bone beneath. A mild caustic then applied to its surface coagulates and destroys the superficial tissues, creates a closely adherent slough which, lying upon that membrane, acts much as a film of collodion would—clings closely to it, holds it down, prevents the return of the blood to the part, reduces hyperæmia, reduces nutrition, and encourages thereby a healthy, nutritive process. That this is a more logical view, more rational, than the one which directs our therapeutic resources toward correction of hypersecretion and the opening of the passages, I think will be generally accepted, and that soon. Certainly in my own experience—and it has not been a small one—I have failed to reach any intelligent comprehension of these diseases on the old theory. But acting on this view of it, directing my therapeutic efforts in this manner, I find myself able, not only in a very large majority of cases to give a favorable prognosis, but to verify the justice of it.

Accepting this view of the action of caustics in the nose, it follows that, what I have many times before claimed, the simple methods, such as chromic acid, possess advantages over the cumbersome and expensive devices, called the galvano-cautery, which should be recognized by all. A crystal of chromic acid accomplishes all that the platinum-wire can possibly accomplish ; accomplishes it in a better manner—it can be applied with far more accuracy, its action controlled with far more delicacy, and it also creates a more efficient slough. While the galvano-cautery, on the other hand, is a cumbersome, expensive, disappointing, troublesome device, and also is not unattended with danger.

It will be noticed that I have confined myself to the discussion of our methods of treating *catarrhal* inflammations of the upper air-passages. This, I take it, comprehends all diseases for which anyone will claim topical applications to be efficacious. The treatment of neoplasms, malignant and benign, syphilis and tuberculosis, paralysis, etc., of course does not properly belong to our subject to-night. Acute catarrhal inflammation I regard as merely a symptom of chronic. Most acute inflammations of mucous membranes nowadays are immediately eliminated by the local use of cocaine. My usual rule is, after the application of cocaine, by which the acute appearances are eliminated, to treat the chronic disease which underlies it.

I think I have gone sufficiently over the ground of our present methods. I may add one word, and keep within the limits of our subject to-night, regarding our elaborate methods of examination.

Soon after Czermak's publication Toboldt presented us with the laryngoscope. We still use it, as well as the elaborate modification by Sass. It presents a very im-

posing appearance in our office. I wish to say here that I do not believe Toboldt's laryngoscope or Sass' involve any optical principle in their construction. I regard them simply as a portentous arrangement of lenses in a metal cylinder, nor do they possess any special advantages as an illuminating apparatus over the head-mirror. Furthermore, as to head-mirrors, every young man twenty years ago who returned from Europe with a full outfit brought with him a five- or six-inch head-mirror mounted on a Schroetter head-band. I have here a small two and a half inch head-mirror mounted on a head rest perhaps one-sixth the size of Schroetter's, which I think possesses every advantage over the large, cumbersome affair of former days. The use of laryngoscopes is largely a delusion. The lenses have little to do with it. A good light renders this little head-mirror here, or Toboldt's laryngoscope, a very powerful aid in a thorough examination. A poor light renders one as well as the other of little account. No possible arrangement of lenses increases the lighting power of any kind of light.

We thus come, at the close of my paper, if my conclusion is right, to this: Elaborate laryngoscopes, elaborate air-pumps, nickel-plated air-receivers, have been of but trifling service to us in the development of our specialty. I hold in my hand a little hand-satchel which I can almost put into my overcoat pocket, which holds apparatus quite as efficient as the most elaborate piece of machinery that is set up in any physician's office in the land. We have ceased to treat by machinery since we have commenced to treat our cases with success.

In former days it would seem almost that the stock-in-trade of an accomplished laryngologist consisted of a large display of nickel plate, with the ability to place a brush into the laryngeal cavity charged with such medicament as fancy might dictate. Now, however, what I think we most demand is a thorough knowledge of the anatomy, physiology, and pathology of the air-passages and their lining membrane, a trained eye to recognize morbid conditions, and a notable amount of manipulative dexterity sufficient to deal with these lesions. In other words, as Dr. Daly very aptly remarked at the Copenhagen Congress: "The sooner we cease to be throat doctors and become throat surgeons" the better will be our success in the management of diseases of the upper air passages.

EFFICIENCY OF MEDICAL TREATMENT OF THE DISEASES OF THE UPPER AIR-PASSAGES.[1]

By ANDREW H. SMITH, M.D.,

NEW YORK.

The question for discussion this evening, as I understand it, is substantially this: How far are the topical measures at present employed in the treatment of the diseases of the upper air-passages, excluding those of a surgical nature, efficient and worthy of confidence? The very fact that this subject is brought forward for discussion shows that doubt has arisen in the minds of some as to whether we are not, to some degree, in error in supposing that the means we are in the habit of employing in these cases do really favorably influence the local conditions.

For my own part, this doubt does not exist as regards acute and subacute affections. Hyperæmia the result of hyperæsthesia is, in my experience, greatly benefited by the local use of anodynes, and especially of a weak solution of carbolic acid. Hyperæmia with little or no hyperæsthesia calls for astringents. A sluggish capillary circulation is benefited by stimulant applications, and mild escharotics are valuable in promoting the healing of abrasions and ulcers.

How very often it happens that a cough which has resisted every kind of internal medication ceases at once when the larynx is touched with a mild silver solution. A slight abrasion of the epithelium which has kept up a constant irritation, is caused to heal at once, and more is effected by a single local application, than a week of internal treatment could accomplish.

The value of disinfectants, anodynes, and anæsthetics, applied to phthisical ulcers and malignant growths, needs scarcely to be alluded to.

But when it comes to the question of the efficiency of local treatment in old chronic cases, and especially in what is known in general parlance as chronic catarrh, I confess that the doubt already alluded to has fixed itself very firmly in my mind.

It was suggested in the first place by the clinical results obtained in dispensary and private practice by myself and by other practitioners, and in the second place by *a priori* considerations as to the difficulty of reaching the whole of the affected surface in the majority of cases, and the still greater difficulty of finding remedies that will remove the diseased conditions, even when the latter are accessible to local applications.

In looking over the last report of one of our large throat clinics, I find that of 1,773 cases treated during the year 1886, 1,351 were cases of non-specific chronic disease, or a little more than seventy-six per cent. In private practice the ratio would probably not be very different. Now, the number of operations undertaken for the relief of these 1,351 cases was 370, or, in other words, only a little more than twenty-seven per cent. of these cases were considered as calling for an operation, or likely to be benefited by one. It follows, therefore, that seventy-three per cent. of the chronic cases were treated mainly, if not wholly, by topical means, exclusive of surgical procedures.

I bring forward these figures in order to show that surgical treatment cannot be made to take the place of other local methods, and that, when surgery has done all that it can do, there still remain nearly three-fourths of the chronic throat and nose cases for the treatment of which we are dependent mostly upon medicaments applied to the diseased surfaces.

Now, the conditions we have to contend with in these cases are for the most part chronic inflammation and its results. We all know how difficult it is to cope satisfactorily with these conditions, occurring in mucous tissues, even when most accessible. The ophthalmologists find in chronic conjunctivitis the opprobrium of their art, the otologists are not seldom baffled by chronic otorrhœa, and chronic inflammation of the uterus affords the chief support of the gynecologist if its treatment adds nothing to his laurels.

And no one who is familiar with the subject will fail to observe that many patients with chronic throat and nose diseases attend for very long periods at the clinics, and eventually give up treatment without having attained anything like a permanent cure. The same is true, also, of private practice. We constantly see and hear of patients attending for a whole winter at the office of this or that throat specialist without being materially benefited, and it must be a pretty frequent experience of any one who works much in this department to find his best efforts in cases of this kind leading to no tangible result.

Under the most favorable conditions all we can do toward promoting the resolution of an inflammation is to assist the reparative efforts of nature. No medicament has been or will be discovered that, by its own action, will dissolve out fibrin effused into the tissues, contract dilated vessels to their normal calibre, or reduce hypertrophied glandular tissue to its natural bulk. These are vital functions, and if influenced at all by therapeutic agents it is only in the way of being modified, not supplanted, by them.

Thus a local stimulant may induce a greater flow of blood to a part, and so bring about a more rapid absorption, or a local sedative may soothe irritated nerve

[1] Read before the New York Academy of Medicine, April 21, 1887.

filaments, and thus lessen hyperæmia. In all these cases, however, there is a tendency to repair by the unaided forces of nature, and what art does is only to develop this tendency. But in cases of long standing it may well be doubted whether this reparative tendency continues to exist; whether abnormality has not come to be the normal condition. Nature makes no effort to restore cicatrical tissue to the condition of the structure it replaces; muscular or glandular elements which have once perished are not renewed; a broken bone badly united does not try to straighten itself. In all these cases the much-talked-of *vis medicatrix naturæ* seems to have "stepped down and out." And when once glandular and vascular and interstitial changes have taken place in a tissue, as the result of long-continued irritation or inflammation, and the structure has thoroughly adapted itself to the new order of things, it may well be questioned whether there remains any tendency toward repair, and whether a change impressed upon the structures from without may not take any other direction as well as that toward the original normal condition.

To illustrate my meaning, let us take an old case of naso-pharyngeal catarrh, the most common disease that the throat specialist, at least in America, is called upon to treat. Here we find the mucous membrane thickened and infiltrated, its vessels enlarged and tortuous, its glands hypertrophied and secreting an excess of mucus, to which vast numbers of leucocytes are added.

This hypersecretion is in keeping with the altered structure, and is as natural to it as the normal secretion is to the normal membrane. Now, what reason have we to suppose that there is an effort constantly going on here to revert to the normal condition, any more than that the cicatrix of a burn is constantly trying to convert itself into normal integument, or the degenerated kidney to evolve new glomeruli or to reopen obliterated vascular channels. I do not believe that such a tendency exists; on the contrary, I believe that the tendency is to a still wider departure from the original condition.

Now, under these circumstances, what rational indication is there for the selection of drugs for local application? How are we to know that this stimulant or that astringent, things that have no natural relation whatever to the structures in question, is going to set right what is wrong, and bring the part again into a healthy condition. It is a sheer assumption, having no ground in reason and, I firmly believe, no justification in experience.

But even if we suppose that such effects are attainable by the local application of remedies, the fact still remains that a large portion of the mucous surface which is drained through the naso-pharyngeal passages is practically inaccessible to such treatment. The membrane lining the frontal and maxillary tissues, and the ethmoidal and sphenoidal cells cannot be reached efficiently by any method of application we possess. Each of these cavities communicates with the nose by a single narrow opening which becomes still narrower whenever the lining membrane is engorged by hyperæmia or thickened by inflammation. These cavities are filled with air which opposes the entrance of anything more. It is true that the frontal and maxillary sinuses may sometimes be injected, but the practice is fraught with so much discomfort and danger that it is very seldom resorted to. Vapors, sprays, and powders are practically excluded from all these regions by the physical conditions above alluded to. So that even if we could correct the abnormal conditions of the portion of the mucous tract within our reach, we should still have the disease intrenched in these remote fastnesses and ready at any time to sally out and regain the territory which had been wrested from it.

But these are not all the difficulties we have to contend with in the topical treatment of the upper air-passages. The diseases located here are for the most part the result of the long-continued operation of causes which are seldom wholly removable. The task set before us is therefore not only to restore the parts to health, but to make them invulnerable. We are required to heal the burn while the hand is held in the fire. Until we know better the causes of these affections and can shield our patients more effectually from these causes, we must be prepared to meet with many disappointments in our efforts to afford relief. As already stated, I do not wish these remarks to be understood as applying to the whole field of the diseases of the upper air-passages, but only to certain chronic forms. Nor do I wish to discourage efforts to relieve even these. I simply wish to insist upon the recognition of certain difficulties and limitations which are inherent, and are not chargeable to faulty methods or want of skill. I wish to insist upon our being just toward ourselves and frank with the public. So long as we are unwilling to meet this question fairly, but seek to evade it by the invention of new methods and new appliances, so long we shall be, perhaps unconsciously, abetting the charlatan and the pretender who live by the credulity of their patrons.

During the years that I have held these convictions and regulated my practice accordingly, the cases in question have brought me much less vexation and dissatisfaction, and also, I am bound to say, much less emolument. Not that I believe them to be entirely proof against intelligent treatment, for simply securing cleanliness will do much good, and the constantly recurring acute exacerbations can nearly always be benefited by sedatives and astringents. Hygienic measures and in some cases internal treatment are also of great value; and in many ways we can be of much use to our patients. But I have long since ceased to expect, as I have ceased to promise, complete and permanent cures.

THERAPEUTICS OF THE UPPER AIR-PASSAGES.[1]

By W. H. THOMSON, M.D.,

NEW YORK.

In complying with the request of the Chairman of the Section on Laryngology and Rhinology to address a few remarks, on the therapeutics of the upper air-passages, to the Academy this evening, I must, of course, deal with the subject from the stand-point of the general practitioner, rather than from that of the specialist. I do this the more cheerfully from my clear conviction that neither of these classes of our profession can do without the other; for I do not believe, on the one hand, that the progress of the medical art is becoming so unmanageable in extent that its field will have to be apportioned into wholly separate divisions, nor, on the other, do I believe that it is possible for the most thoroughly equipped physician to be able to do all that can be done for every patient without special help.

Shortly put, the case stands thus: The unity of the body renders the general practitioner useful to the specialist, while the complexity of the body renders the specialist often an indispensable associate to the general practitioner.

I begin, therefore, with the statement that, in my opinion, the treatment of chronic diseases of the upper air-passages should be directed chiefly by two principles, viz.: first, by taking cognizance of cutaneous nerve-associations in the causation and in the perpetuation of inflammations of mucous membranes; and, second, local disinfection.

First.—It can scarcely be questioned that the inhalation of irritating air is rarely the cause of either acute or chronic inflammations of the respiratory passages, except in the instances where infecting germs, as in pertussis, etc., are thus introduced. Rather we would say that some quite *local* chill of the surface is the occasion of a coryza or a pharyngitis or a tracheitis ten times to a direct irritation of the respiratory tract once. The peculiarity

[1] Read before the New York Academy of Medicine, April 21, 1887.

here, which is of great significance, though unknown in its mode of production, is that the internal disorders are not caused so much by general, but rather by very partial, external exposure. The whole body may be wet in a rain-storm, but no cold is thus caught with anything like the frequency that it is from sitting for some time with damp feet alone, while the rest of the body is warm and dry. On a winter day one may find the cold air blowing through a keyhole on the back of his neck give him a coryza which no walk would in the bitter wind itself. But while we cannot yet indicate all the steps in the causation of these familiar effects, yet a brief consideration may not be out of place of three laws of nervo-vascular association which may have some bearing on the question how internal congestions or inflammations follow upon external impressions.

The first law is that organs which exist in symmetrical pairs, such as the hands, the feet, the eyes, and the ears, are so closely associated in their vaso-motor relations that the same effect, so far as their circulation is concerned, is produced in both by an impression made only on one member of the pair. Thus Brown-Séquard showed that a thermometer held in one hand will drop 14° F. if the other hand be dipped in ice-water, while a thermometer in the axilla at the same time will mark no difference. On one occasion I made use of this fact while endeavoring to find the bleeding vessel in a pistol-wound through the palm of the hand, for as soon as the other hand was dipped in ice-water the bleeding was checked enough to make the examination much easier. In like manner, if the tip of one of the translucent ears of a rabbit be sharply pinched, the pulsating arteries in the other ear will at once contract into invisibility. It is on this principle that injury to one eye is so dangerous to the integrity of its fellow by consecutive inflammation.

It is fortunate that organs that are not in symmetrical pairs, as the lungs and the kidneys, do not show anything like such a close nervo-vascular association.

The second law is that there is a close association between the sensory nerves of any part of the skin with the vaso-motor nerves of the organs or viscera which are immediately within that part, so that like impressions on the cutaneous nerves produce like effects on the circulation of the inner structures. Thus, if a cold hand be suddenly laid upon the præcordium, the heart will give a bound and for a moment stop; so a cold hand laid on the abdomen will cause the uterus to contract; a dash of ether-spray on the chest is the quickest way to cause a hæmoptysis to stop, and I myself have often used a cold hand for the diagnosis of incipient phthisis. It may be tried by dipping the patient's own hand in cold water, so that he will not be so afraid of the procedure, and then laying it alternately over the right and left apex; if done suddenly he gives a short cough when the impression of cold is made on the affected side, but not when the application is made on the other. We need not multiply these examples, for this principle is illustrated in the recourse to all surface applications in internal disorders, such as rubefacients, blisters, and faradism to stimulate absorption, or poultices, etc., to allay irritation. No physician, in fact, should neglect cutaneous protection in all acute internal inflammations, such as pericarditis, pleuritis, etc., and I always give many details for such purposes in every case of phthisis or chronic bronchitis.

The third law is that there are certain special vaso-motor associations of widely separated parts which have no obvious functional connection with each other. The first of these which we would mention is between the vaso-motor nerves of the pelvic viscera and those of the feet. Thus, girls can stop menstruation by putting their feet in cold water, while, on the other hand, there is no emmenagogue which at all equals persistent application of dry heat to the feet; so also we find in males with an irritable stricture of the urethra, or an enlarged prostate, that nothing aggravates their infirmity so much as getting the feet wet or cold. On the same principle, if surgeons are troubled with bleeding in cutting for stone in an old case of vesical irritation, putting the feet in cold water will suspend the hemorrhage, as in the case of palmar wounds, above referred to. Again, irritation in the pelvis contracts the femoral artery; so that coldness and anæmia of the feet is the rule in all instances of ovarian irritation in women, and in cystitis or prolapse of the rectum, etc., in men.

Another such association, which bears more immediately on our subject, is between the feet and the circulation of the pharynx and larynx. Putting the feet in cold water is followed by an immediate paleness of the pharyngeal mucous membrane in contrast with the rest of the mucous membrane of the mouth. I should like to have this observation tested by others; for I am convinced that this association is quite unmistakable and peculiar, and best shown in normal cases.

Still another is between the nape of the neck and the circulation of the nasal cavity. While the relations of the cervical sympathetic, of course, are known to be very wide in the control of the circulation of the face, head, and throat, yet the close dependence of congestions of the nasal cavity on abnormal innervation of the cervical nerves has not been as fully recognized as I think it should in the management of some of the obstinate maladies of a region in which vascular disorders are so apt to be tedious, because we have so little muscular tissue to aid in restoring tone to the affected structures.

The limits of my paper, of course, will not allow me to follow up the statement or illustrations of principles further now than to say that we may expect in disease to find healthy nerve functions or properties often exaggerated to the degree of becoming serious complications which must be taken into account when we come to treatment.

Thus, no one would, *à priori*, have guessed that a healthy irritability of the sensory nerves of the bronchial mucous membrane may become so heightened in asthmatics that the mere presence of a little powdered ipecac in a room, or of buckwheat in a lower story, or the presence of a single cat in the house, would cause a sense of suffocation to set in immediately. But I have been satisfied from observation that many persons with chronic mucous catarrhs are affected by external influences which are wholly inappreciable by persons in health. We all of us, probably, have had a bad cold in the head on some occasion, which caused us to ask what door or window down-stairs was left open, when no one else perceived that a streak of cold air was stealing in from somewhere; and in chronic cases of nasal, pharyngeal, or laryngeal catarrh I am sure that many a patient has his trouble aggravated by a nocturnal exposure in bed of the neck or back of the shoulder which no healthy person would feel at all.

Hence, as regards treatment, I would say, first, that unfortunately we have but very few vaso-motor tonics or strengtheners, and for this particular weakness—for irritability is weakness—I know of nothing which will compare with the application of cold. The cold douche to the nape of the neck on rising, great care having been taken to keep the hair of the back of the head from being even dampened by the water, and cold salt-water sponging of the throat are measures which should be kept up for months together, in all affections of the upper air-passages. After the reaction from the douche is established and the skin is dried, the entire surface of the front and back of the neck and of the root of the neck, on the one hand, and then of the back of the shoulders, ought to be well rubbed with sweet olive-oil, to lessen the tendency to perspiration, or at least to check the chilling effects of rapid evaporation of the perspiration, which oils certainly do.

Our next indication is to protect the sensitive surface by special covering. Not only is muscular rheumatism strikingly benefited by sleeping in woollen night-shirts

and between woollen sheets, but I am sure that affections of the upper air-passages will be equally favorably affected by this measure, for I have repeatedly tried it. During the daytime a light woollen undergarment should be worn next to the skin, and over this a perforated buckskin shirt, made high in the neck before and behind and long in the sleeves. I cannot speak too highly of these buckskin protectors, not only in phthisis and bronchitis, but also in all chronic catarrhal affections. In my experience they are far superior to thick flannel underwear, and are to be dispensed with only during the really hot weather of summer. I have seen the same good results from buckskin drawers in cases of chronic diarrhœa and cystitis, which lead me to prefer this material to any other as a protective. The use, on the other hand, of partial coverings, like many of the chest-protectors which we find on our patients, I regard as almost worse than useless.

Second.—As to local disinfection. We are certainly living in an era of medicine in which it is difficult to keep one's head level in the midst of such a rush of discoveries and of pseudo-discoveries. Nevertheless, it is impossible to resist the steadily increasing mass of evidence, that purulent inflammation, as such, is always the result of infection. The demonstrations lately shown us by our distinguished fellow-academician, Dr. Herman Knapp, that rabbits' eyes operated on by the best-kept surgical blades by the best operator yet become disorganized by purulent inflammation, while eyes lacerated by rough pieces of iron heal without a trace if only the iron be sterilized first in the lamp-flame, are but in keeping with a multitude of similar positive proofs that no weakened living tissue—whether weakened traumatically, or weakened in its innervation, or weakened in its nutrition—can exist in our atmosphere without being at once attacked, not by chemistry, but by life. We are everywhere and always exposed to powerful living enemies, which have only recently been made visible to us, and we are safe in whole or in part against them only as we can keep up in whole or in part that resistant power which we call life. As soon, in other words, as a particular tissue begins to lose its normal amount of vitality, the enemy finds it out and begins the attack.

Now, the great difficulty in the treatment of chronic mucous inflammations doubtless lies in this very direction, owing to the structure of the tissue itself. For example, the micrococcus of gonorrhœa has a habit of retiring into the deep follicles and crypts of the urethra, where injections cannot follow. One germicide after another may be tried, and the canal will seem for a while to be thoroughly disinfected and cured; but after a time the reappearance of the gleety secretion shows that another generation of the coccus has come forth from some hiding-place to occupy the field again.

That the mucous membrane of the upper respiratory passages should be exposed above all others to these atmospheric intruders is of course obvious. In fact, many of them are visible enough, as the aphthæ in the dying frame of the consumptive. Others are plainly to be inferred as frequent visitors, as in the case of the communicable influenzas, or colds, which daily meet us, invading a family and spreading from one member of it to another. So, also, the clinical features of hay-asthma can be satisfactorily explained in no other way; but the most practical deduction is this—that, as pus can be prevented only by excluding germs, so all chronic mucous inflammations can be got rid of only by excluding the presence or preventing the activity of germs.

We may do this, I imagine, in two ways. One is by improving the resisting power of the tissues. Under this head would come the removal of all weakening influences, some of which we have already referred to—namely, by attending to local vascular innervation; another is by dealing with hereditary weakness of particular tissues which predisposes them to be attacked by invaders. Increased nerve- and cell-nutrition by cod-liver oil is an example of meeting this indication.

The second way is to use disinfectants directly. Here we may say that so recent is this whole subject, in its bearing on the etiology and treatment of disease to the profession at large, that we need not be surprised if our methods of attempted disinfection of the air-passages are both crude and ineffective. The chief obstacle in our way lies in our inability to prolong the employment of the disinfectants enough to be of any real service. An ideal respiratory disinfectant would be an ingredient of the air breathed continuously night and day for a week or more. Such a disinfectant is the air of the ocean several hundred miles out, or of certain mountain localities against the germ of hay-asthma. I believe that some such disinfectant will yet be found against the tubercle bacillus; but when we turn to attempts to fill the nostrils with vapors or insufflations, or the pharynx or larynx with spray, we are met at the outset with the difficulty of temporary effects—temporary either because to secure permanent effects the concentrated agents would be too irritating, or else from the impossibility of having our patients keep up voluntary inspiratory efforts for more than a few minutes. Nevertheless, it is in this direction that I look for the greatest progress to be made yet in the therapeutics of the upper air-passages. Undoubtedly a certain proportion of cases are dependent upon malformations, congenital or acquired, occurring in the nasal channels, and in them surgical measures promise the readiest relief; but otherwise the greatest advances will be made, I imagine, by discovering both how to use disinfectants and what disinfectants to use.

With respect to this latter indication, I would remark that there is considerable room for observation. I have long been satisfied that the carbolic-acid class of disinfectants has special applications, but not universal ones, and that for certain common purposes this class is much inferior to others. By the carbolic-acid class I mean derivatives, natural or artificial, from woody or vegetable tissues. All coal-tar derivatives come under this head, and also those products in nature whose purpose is evidently to keep the seeds or bark or texture of the plant from being attacked, such as the spices, camphorous and aromatic secretions, also salicin, quinine, etc. These numerous agents are all closely allied, both in their physiological effects on the human nervous system and on the temperature of the body, and as disinfectants they are the best for this one particular object—namely, for all suppurative disorders.

For necrotic affections, on the other hand, they are decidedly inferior to the chlorine class. This class is a chemical order of disinfectants which acts by the double process of affinity for hydrogen, causing it to kill fungi by decomposing the water of their tissues to get the hydrogen, while at the same time it sets free nascent oxygen, a no less powerful disinfecting agent in its way. To this class belong chlorine, iodine, bromine, and sulphur, and whenever we have a non-purulent secretion with malign odor, as in bone-necrosis and in many chronic thin mucous discharges, the steady employment of some member of this class promises, I think, much better results than any of the carbolic-acid class.

I have long used insufflations of calomel in bismuth in nasal catarrh, for disinfection, and have never yet seen any injury from them. I prefer this also as a means of affecting the pharynx through the nose, because of the greater adhesiveness of the powder on the parts than articles used in spray-solution. But as I doubt not that the Academy will have much more extensive and varied information about such measures from others, I will now close by saying that, with the principles of treatment established on much superior premises than was possible in former times, we have every reason to expect great triumphs in the healing of affections long the despair of our art.

THE Post-Graduate schools of this city are in a very flourishing condition, the classes being larger than ever.

A PAPER CONCERNING A FEW POINTS IN PRACTICAL LARYNGOLOGICAL AND RHINOLOGICAL WORK.[1]

By H. HOLBROOK CURTIS, M.D.,

NEW YORK.

The following conclusions have been deduced from a close observation of over one thousand cases in which I have practised the enlargement of the upper air-passages, viz., the restitution of their normal calibre by means of the employment of chromic acid to erectile tumefactions and true hypertrophies; or surgical interference to remove cartilaginous or bony obstructions caused by septal deflection, etc.

Subacute catarrhal inflammation is present in all cases where there has existed for some time a nasal stenosis due to deviations of the septum or to hypertrophy of the turbinated bodies, or to erectile tumefactions due either to over-stimulation of the normal erectile tissue of the turbinated bodies or a lack of vaso-motor resiliency, allowing permanent dilatation of the venous plexuses therein contained. This subacute catarrhal inflammation extends to the pharynx and is generally accompanied by more or less glandular hypertrophy in the post-pharyngeal wall. This so-called granular condition of the posterior wall is due to mouth-breathing, and immediately subsides upon the free opening up of the nasal channels.

The more occluded the air-passages of the nose, the more extensive the glandular hypertrophies in the pharynx. Any treatment directed to these glandular masses without enlargement of the nasal fossæ is misdirected.

Chronic post-nasal catarrh unaccompanied by stenosis does not exist. Conditions that simulate this may be usually referred to disease of the ethmoid cells, especially in the anterior group.

Disease of the ethmoid cells is generally due to a hypertrophy of the middle turbinated bone and consequent occlusion of the exit of ethmoidal secretions.

The treatment of this most obstinate condition should consist in the application of chromic acid to the thickened middle turbinated body which is found to impinge on the external wall of the middle meatus, in order to allow of a free exit to the secretions of the anterior ethmoidal cells and a proper oxygenation of the cavity. By passing a thin flat probe between the pendulous-thickened middle turbinated body and the outer wall we demonstrate the existence of this retained muco-purulent secretion—a condition frequently overlooked by simple examination with the nasal speculum. The symptoms of this disease are those of ordinary chronic rhinitis, with perhaps more fulness attributed to the cribriform region, with free expulsion of the secretion at intervals into the pharynx. The patient will also blow the nose and entirely free the cavities, so far as an examination reveals, but often in a few moments will again have a copious discharge upon the handkerchief. When the disease has to do with the posterior ethmoid cells, the tenacious secretions are poured down between the middle turbinated body and the septum, coming from the superior meatus. This complication is easy to diagnose, but I consider it of rarer occurrence. I introduce this disease to elucidate what many writers consider a post-nasal catarrh.

I have made application of chromic acid to the inferior turbinated bodies for the past six years in my private and dispensary practice, and do not remember a case that has come to me for treatment for catarrh during that time, in which there was found to be hypertrophy or erectile tumefactions, where I have not employed it to the exclusion of all other escharotics.

So great is the importance, in my estimation, of a re-establishment of the air-current through the upper air-passages, and particularly through the inferior meati, in the treatment of all the affections of the larynx, non-specific or non-tubercular—and I say it with all premeditation—that I would not to day exchange the flat probe and chromic acid for the combined douches, sprays, and therapy of the best laryngological establishment. In saying this I would not, however, depreciate the employment of the spray as an adjunct to treatment.

In estimating the effects of enlarging the upper air-passages on the larynx and vocal bands, I would state that quite a number of professional singers have applied to me for the operation of "burning the nose," simply for the direct improvement of quality or *timbre* in the vocal resonance, so magical is the effect upon the voice. To sum up the benefits of the operation to the patient, we find comparative immunity from cold in the head and sore throat, softening of a dry post-pharynx, disappearance of glandular hypertrophy in the pharyngeal wall, and glosso epiglottic fossæ, disappearance of chronic congested conditions of the vocal bands causing huskiness of voice, relief to bronchitis, acute and chronic, relief of spasmodic asthma (sometimes immediate), and great strengthening of the power and endurance of the voice. A voice that has become cold and hard will in a day or two regain its sympathy and musical quality after an enlargement of the air-passages. Destruction of the erectile tumefactions, unless true hypertrophy exists, is not necessary, for when the erectile bodies become permanently dilated by paresis of the inhibitory nerve-force of the sympathetic ganglion (or acted upon by a permanent reflex impression from a correlated area, causing partial paralysis of the efferent vaso-motor fibrillæ), it is only necessary to use the acid in such quantity that a cicatricial envelope be superposed which will act as a bandage or retaining-wall to the dilated vascular plexus and permit the fossæ to remain unobstructed. That the correlated areas are in reflex sympathy directly by influence exerted through the chain of sympathetic ganglia seems to me to account for the direct impression imparted to the vocal cords by applying chromic acid to the turbinated bodies. The question of remote reflex phenomena has been the subject of much research by Woakes, Mackenzie, and others, and their theories are certainly borne out in my experiments. In no other way can I account for an immediate effect on the membrane covering the vocal cords. I would cite a case to illustrate:

Miss H——, a prima donna, presented herself on the occasion of a special performance in which she wished to appear to advantage. Vocal bands slightly congested, slight erectile tumors at anterior aspect of inferior turbinated bones; no pharyngitis worth noting. Said singing was a great effort, and she feared her inability to perform. I used chromic acid freely to the anterior enlargements, and was surprised to find her voice markedly improve at once, and she told me the following day she had made a brilliant performance.

Since that time the patient has, on two occasions, come to me from Philadelphia between performances to have chromic acid applied when, in her words, her voice was "used up," and she tells me that it always restores the brilliancy of tone, though there seems to be no necessity for the operation. I have on many occasions repeated this upon other singers with the same result.

This is manifestly a reflex impression and bears a striking relation to the immediate relief sometimes afforded in spasmodic asthma upon attacking the turbinated tissues with an escharotic. To illustrate a class of cases to show the effect on hoarseness due to subacute catarrhal laryngitis, I cite the following:

Miss C——, the leading lady in one of our theatres, had suffered from recurrent attacks of hoarseness for two years, and had been afflicted with hay asthma during the last six seasons. I found stenosis of both nostrils almost complete, due to erectile hypertrophies, granular pharyngitis, and subacute laryngitis. She had been treated almost daily with astringent sprays and inhalations. I stopped all applications to the larynx and

[1] Read before the New York Academy of Medicine, April 21, 1887.

freely destroyed the superabundant tissues, using the nasal saw to correct a slight anterior cartilaginous tumor of the septum. In a few days her voice was entirely restored. The treatment was continued at intervals of ten days for six consultations. The patient informed me a few days since that from the first application she had never been hoarse, now over a year ago, and she had escaped asthma during the summer of last year, though her eyes were somewhat affected during the corresponding period of her previous attacks. My case-book records very many parallel cases, and the wonderful relief afforded in cases of spasmodic asthma by this simple operation is a source of constant gratification

So much, however, has been written on the subject that it seems hardly worth while to allude to it here.

As to bad results from the employment of chromic acid, I have seen none. The acid should be carefully used, a deliquesced solution smeared on one side of a flat copper applicator, and a few moments after making the application to the tissues it should be washed off with a Dobell spray. A little care must be taken not to bring the acid in contact with the soft tissues of the palate, or a painful uvulitis may result.

True hypertrophies, which are of rare occurence and frequently need the trephine or saw to assist in their removal, seldom return. Erectile tumefactions which do not deal with proliferation, but simply dilatation, sometimes need cicatrizing once a year. A majority of these cases, however, are either permanently cured, or await exciting causes, such as continued colds, etc., for their recurrence.

From even my own rather limited experience I think that aurists have not as yet become cognizant of the enormous advantages to be obtained from the restitution of the lower, and especially the lowest, air-tract of the nose. The inferior meatus is the true oxygenator of the Eustachian tubes, and a deflection of the air-current to the middle meatus is, according to several authorities, often the origin of aural complications.

That the relief of obstinate tinnitus is ofttimes assured upon re-establishing the nasal respiratory function in the proper channels is unquestionably true, and this I find will often cure tinnitus after many other means have been attempted. I am at a loss to explain whether this is by reflex sympathetic action or by simply directing a stream of air into the Eustachian orifices, for, by a deflection of the nasal respiratory current to the middle meati, some writers contend that a vacuum may be produced by the air rushing downward over the projecting prominence of the tube, and thereby cause concavity of the tympanum and associated troubles. This subject I prefer to leave for another occasion. The reflex symptoms caused by polypi, which usually are attached to the middle turbinated body, are an exaggerated type of those reflexes which are, generally speaking, associated with stenosis. Operative procedure I have not touched upon ; but the results obtained by the application of the saw and trephine to the deviated septum are coincident with those of relieving the commoner forms of stenosis.

To conclude I would say that the sooner the farce of applying strong astringent solutions and nitrate of silver to the larynx and upper air-passages is done away with, and the proper appreciation given to the magnificent results obtained by restoring the function of respiration, as nature intended, the sooner laryngology will be placed on a higher plane, and an immediate relief given to countless thousands who imagine an incurable, so-called, post-nasal catarrh.

TOPICAL APPLICATION TO THE UPPER AIR-PASSAGES.[1]

By WILLIAM CHAPMAN JARVIS, M.D.,

new york.

Although the question of topical medication as applied to the upper air-passages has already received much attention, a discussion of its comparative value cannot fail to prove profitable, on account of the modifying influence which has been recently exerted by the great advances in nasal surgery. Foremost among the means employed for the treatment of affections of the upper air-passages stands compressed air. A pump and air-reservoir capable of withstanding great pressure are required to render this therapeutic medium serviceable. No argument is necessary to prove that the value of the spray has been greatly over-estimated in prescription and practice. It is quite possible that the confidence evinced by the advocates of this measure can, in part, be attributed to the scanty and unsatisfactory surgical measures at the physcian's disposal during several years following the period of its introduction as a therapeutic agent. That the spray-producer still subserves a useful purpose cannot be safely denied. I believe, furthermore, it is possible to determine the extent of the spray-producer's usefulness and to name the several conditions which indicate its employment. I consider it the most useful means we possess for the application of cocaine-solutions. It may occasionally be employed for cleansing purposes, and, even in the nostril, is sometimes preferable to the douche ; it offers us the only medium for the production of rhigolene anæsthesia ; it affords us a useful means for the application of the various preparations of vaseline, and can be profitably employed for the projection of medicated powders. A great deal of confusion seems to exist in regard to the true significance of pounds pressure. When speaking of compressed air, ten, twenty, thirty pounds mean nothing until we ascertain the size of the spray-tube's orifice. Thirty pounds pressure behind a tube with an orifice of one one-hundredth of an inch means a gentle spray ; the same, through an orifice of one-eighth of an inch in diameter, forms a powerful, intolerable blast. Hence, I think, one should always designate the dimensions of the orifice of escape in speaking of pounds pressure. My standard of pressure varies between ten and fifteen pounds. For cleansing purposes, I employ sprays whose orifices vary from one-sixteenth to one eighth of an inch.

Coarse sprays, when employed intelligently, constitute one of the most effective and agreeable means in our possession for cleansing the nasal cavities. The syringe-like action of the projected fluid is re-enforced by the mechanical effects of the compressed air. There is less danger from the entrance of fluid into the middle ear, a fact which determines its sole employment in certain cases. The spray-producer is valuable more as a means for obtaining relief than as an instrument for producing a cure, when considered *per se*. The utility of the syringe, however, is unquestionable, and in many instances it is to be preferred to the spray. Compressed air affords us a most valuable means for the satisfactory employment of medicated powders. The therapeutic action of powders, and particularly of iodoform, is promoted by the remarkably fine state of sub-division attained when they are applied according to the method of Ely.

In the employment of that most reliable and efficient of all intra nasal anæsthetics, namely rhigolene, and especially in the treatment of gelatinous polypi and turbinated hypertrophies, with the fluid, we rely upon compressed air as the only means for obtaining the benefits of this agent. Spray-tubes with very small orifices, $\frac{1}{32}$ to $\frac{1}{100}$ of an inch in diameter, are required for the production of rhigolene anæsthesia, in order to avoid the excessive escape of fluid.

---

[1] Remarks made before the New York Academy of Medicine, April 21, 1887.

Inasmuch as the vast majority of catarrhal processes in the nasal cavities are due to nasal obstruction, and its natural results, impeded respiration and disturbances to nasal drainage, we must rely upon the practice of special surgical procedures, which have for their purpose the restoration of nasal respiration and normal drainage. I have already pointed out that excess of nasal mucus was due more to the inspiration of accumulated discharges from irregular conformation than from a true hypersecretion.

As regards the use of chromic acid, while I promptly recognize some of the good results which follow the employment of this therapeutic agent, its remarkable solvent action, for example, when applied to laryngeal papillomata, I find it impossible to subscribe myself in favor of its employment for the removal of turbinated hypertrophies. That chromic acid is capable of reducing turbinated hypertrophies, if persistently applied, cannot be doubted for a moment, but that it is the best therapeutic agent for this purpose must, in view of ample contradictory evidence at hand, be emphatically questioned. I have met with several forms of more or less severe annoyance where this agent has been employed, from the common traumatic rhinitis to extensive inflammation of the post nasal structures and œdema of the soft palate. I cannot understand why the employment of this caustic should be persisted in, for many days at a time, with the object of removing a small turbinated hypertrophy, when it is always possible to transfix the redundant tissue by means of a slender needle, and remove it by means of the snare-écraseur in a few minutes, with no inconvenient after-effects. The same statement applies with even greater force to the galvano-cautery.

There are many more interesting points relating to the subject, the consideration of which I feel compelled to omit on account of the necessary limitation in time.

Progress of Medical Science.

Paroxysmal Tachycardia.—In a recent lecture, Nothnagel directed attention to a case of "paroxysmal tachycardia, combined with failure of the heart." On the forenoon of October 6th, 1886, the patient, aged thirty-six, was admitted into the hospital, his pulse-rate being at that time 120 in the minute. In the afternoon it was 144; on the next morning, 90; during the following day 84 and 82; on October 9th, morning, 82; in the afternoon, 138; on the morning of October 10th, 178; at eleven o'clock the same day 170, and soon afterward 182; on the morning of October 11th 84, at half-past ten o'clock 176, at four o'clock 132, at five o'clock 144; the next morning at eight o'clock it was 176, at nine o'clock 144, at ten o'clock 146, at eleven o'clock 134, at mid-day 144, at four o'clock 168, in the evening 164; on October 13th it was 92 in the morning, at nine o'clock 88, and soon afterward from 170 to 180. This acceleration of the pulsations lasted from half-past one till half-past three; at five o'clock the patient's pulse was 96. On October 14th it was 72; on the 15th 76, and so on, the number of the pulsations being again normal. The temperature was normal throughout. The patient was seized with these paroxysmal attacks without any apparent cause, and they were very variable in duration. On one occasion the paroxysm lasted for two hours, another time about two days; the longest duration was from three to four days; the average duration was from one to one and a-half day. The attacks occurred without any artificial stimulant whatever, such as coffee or tea, nor were they caused by any psychical irritation; they showed no gradual transition, but came on and ceased quite abruptly. The patient happened once to be seized with a paroxysm of 176 beats immediately after laying down a book, the contents of which had not interested him in the least. The attack was accompanied with a feeling of anxiety, but Professor Nothnagel emphasized the fact that this anxiety was not such as was met with in angina pectoris. All the other characteristic symptoms of that affection were absent in the case in question. The attack disappeared quite suddenly, and the patient stated that he had then the feeling "as if something would fall away." The patient further stated that he "sometimes succeeded in suppressing the attack by a deep and prolonged inspiration, especially if he at the same time drank a glass of cold water." Professor Nothnagel told the patient to do this during an attack, and after the patient had swallowed half a glass, Professor Nothnagel was able to state that the number of the pulse-beats had decreased quite suddenly; he felt three slow and large beats, and soon afterward the number of the beats was again about 180. Professor Nothnagel also made other experiments; he told the patient to swallow a spoonful of common salt; he compressed the crural nerve very strongly, and wound a thread around the upper extremity, but these manipulations produced no effect. The patient himself stated that the draught of cold water had not much to do with the cessation of the attack, but that it was chiefly due to the deep inspiration. Professor Nothnagel remarked that some cases of paroxysmal tachycardia were to be found recorded, but that paroxysmal tachycardia in cases of organic heart-disease were very rare, and that he did not remember any similar case in medical literature. As to the explanation of this phenomenon, the lecturer said that of course there was no doubt that one had to do in such a case with a disturbance of innervation, but that the question as to what nerve-tracts were affected was very difficult to answer. As to the existence of an accellerator-nerve of the heart in the human species, this was still a matter of dispute. Only two nerve-systems could be taken into consideration in the case in question—the pneumogastric and the musculo-motor apparatus in the heart. It was conceivable that there might be some irritation of the cardiac musculo-motor apparatus in the substance of the heart itself; or again, there might be sudden paresis of the vagus. It was very difficult to decide which explanation was correct in this case, but according to the impression the lecturer had received from the observation of one of the attacks, he was rather inclined to the latter view. One might suggest that, in the same way that intermittent paralysis occurred in other motor nerves, such intermittent functional paralysis might also occur in the vagus. Professor Nothnagel thought it very probable that this hypothesis was correct.—*The British Medical Journal.*

Hyoscine in Kidney Disease.—Dr. Tisard, of London, believes (*The Practitioner*, February, 1887) that hydriodate of hyoscine is a drug which can be used with perfect safety in cases of kidney disease where morphine is inadmissible. It is a drug which may give rest when other sedatives fail. He also states that if used in two-minim doses, subcutaneously, it may give more satisfaction to the patient than to the attendants, since the unconsciousness may be accompanied by angry and combative delirium; should this occur it will probably be sufficient to diminish the amount employed. It is very rapid in its action, unconsciousness following in from ten to twenty minutes, and the after-effects are of a soothing character. Even when delirium is present in a violent form, it is followed by quiet sleep, and the patient, being unconscious, is much more refreshed than by a night of short snatches of sleep produced by chloral or bromide, and the result is a marked improvement in both aspect and temper. No irritation is produced around the site of injection.

Early Dentition.—Dr. Frank Groat, of Fremont, O., reports the case of a child, born in 1855, who had four lower incisors at birth. The parents were English, and there was nothing in the condition of the mother to account for the phenomenon.

A NEW ERA IN THE THERAPEUTICS OF PULMONARY PHTHISIS.

THE discovery of the tubercle bacillus, as soon as its importance came to be fully realized, gave a new impetus to the efforts of those who had been occupied in what seemed to be the vain task of searching for some means of curing pulmonary consumption. If the cause were known, it seemed so simple a problem to apply the remedy. The remedy, indeed, was found—many remedies were found—but the difficulty was in their application. Many methods have been tried, some of them most ingenious in their conception, with more or less encouraging results. It may, perhaps, be of interest to our readers to review briefly the methods thus far proposed, to see what advances have been made, and to learn what is the hope of ultimate success in the cure of this scourge of man and beast.

Antiseptic substances had been given empirically long before the parasitic nature of the disease had been discovered, but now they were given with greater hope, though not always with greater success. It was soon recognized that the internal administration of germicidal remedies could exert but little curative effect on the local disease, and the attempt was made to apply the remedies directly to the seat of the affection in the lung itself. The different methods employed to effect this object may be divided into several groups. We have (1) the internal administration of substances excreted chiefly by the lungs; (2) inhalations; (3) intra-pulmonary injections; (4) gaseous rectal injections, and (5) the more strictly surgical procedure of incision into the cavity, evacuation, and drainage.

Among internal remedies, arsenic enjoyed a reputation long before the rise of the theories now in vogue, and it still holds its ground as a valuable tonic, even though its germicidal power in small doses may well be doubted. Tannin, in daily doses of from thirty to sixty grains, has also been recommended in the strongest terms by Arthaud and Raymond. Filleau gives carbolic acid, in doses of two grains every day or two, hypodermatically. He was led to employ it thus on the ground that the drug is largely excreted by the lungs, and he reports a number of successful cases. He never saw any serious toxic symptoms produced.

Naturally, inhalation has been the most frequently resorted to, as seeming to offer a simple and efficacious means of applying antiseptic substances directly to the focus of disease. The list of drugs so employed embraces nearly all the antiseptics and germicides known to medicine. Corrosive sublimate, hydrofluoric acid, anilin, naphthalin, sulphurous acid, iodoform, menthol, and camphor are only a few of the many which have been vaunted as specifics by various enthusiasts in all parts of the globe. Experiments have demonstrated two facts, however, which argue against the probability of much benefit being derived from inhalations. In the first place, the tubercle bacillus is destroyed with considerable difficulty, the ordinary antiseptic solutions having but little effect upon it. Then, again, the vapor or spray is not likely to penetrate far enough to reach the bacilli whose destruction is sought, unless it is driven in under a strong pressure, for the production of which expensive apparatus is needed.

The ingenious conception of Cantani should be mentioned here. He endeavored to effect the destruction of the tubercle bacilli by means of inhalations of pure cultures of bacterium termo, as experiments outside the body had shown that these two forms of micro-organisms were mutually inimical. These attempts, however, were not encouraging enough in their results to lead to many repetitions.

The introduction of microbicidal agents by means of injections into the lung-substance at the seat of the lesion is a more rational measure, and seems to be of greater promise than those above mentioned. These intra-pulmonary injections were, it is true, practised by Dr. Pepper long before Koch's discovery was published to the world. He injected a dilute solution of iodine with the object of favorably modifying the morbid process. But it is since the new theories of tuberculosis have come into vogue that this method has found most favor. When properly made, these injections seem to be devoid of danger and do appear to alleviate the more urgent symptoms, if nothing more. But those who have had the most experience with this method hope for more than palliation, and even look forward to permanent cures. The drugs that have been employed in this way rival in number those given by inhalation. A modification of this method is that of Riva, to which we referred very recently in these columns. He is not satisfied with the injection of a few drops of the antiseptic fluid, but seeks to bathe the entire parenchyma of the lung in the vicinity of the tubercular focus with the bacillus-destroying solution. It is not possible yet to determine whether this modification possesses any practical superiority over the older method of injection.

We have finally to notice the treatment of advanced pulmonary tuberculosis by incision and drainage of the cavity. This method is even older than that of intra-pulmonary injection, having been practised in the early part of this century. It has the appearance of being a formidable operation, and comparatively few have had the temerity to attempt it. The advocates of the operation argue that tuberculosis of the lung is as strictly a local process as tuberculosis of a bone, and is as certainly relieved by surgical measures. Some of the cases operated upon would seem to have justified these views by the results obtained, while others have been less happy in their sequel.

It is certainly very encouraging to see so much activity in this direction, and the hope of eventually bringing pulmonary phthisis into the class of curable diseases seems to be not without foundation. But, nevertheless, it is wise not to be too sanguine, and we may well close this hasty review of the modern therapy of phthisis with the words of Dr. Pollock, uttered at the conclusion of the Croonian lectures for 1883. "No parasitic theory," he says, "can lessen the importance of the use of tonics and cod-liver oil. Supposing we possessed a local remedy of sufficient power to insure the destruction of such bacilli as are met with in the secretions, their rapid reproduction would soon overtake our treatment." And the same may be said even after we have destroyed all the bacilli present in the lung-tissue. Until we have succeeded in overcoming the predisposition to the disease we are liable to disappointment in witnessing a speedy return of the malady which we had congratulated ourselves had been thoroughly and entirely eradicated.

THE QUESTION OF OPERATION IN PERITONITIS.

A GREAT change has taken place in recent years in the minds of surgeons as to the dangers of abdominal section. While formerly the peritoneum was regarded as a *noli me tangere*, only to be incised as a last resort in desperate cases, surgeons now feel scarcely any more compunction in opening the abdomen than in removing the breast or amputating a foot. Exploratory incisions are almost of everyday occurrence, and, speaking generally, the results of such operations seem to justify the contempt which is felt for the formerly dreaded peritoneum. Not only is operation resorted to for the removal of tumors and for the relief of other troubles falling legitimately within the province of the surgeon, but even in so-called idiopathic peritonitis it has been proposed to open the abdominal cavity and provide exit for the products of inflammation, and the operation has actually been done several times.

Dr. Albert, writing in the *Allgemeine Wiener Medizinische Zeitung*, No. 10, 1887, discusses the question of operation in peritonitis, and considers briefly the indications for its performance. Leaving aside the subject of exploratory incisions and operations for the removal of tumors and the relief of other diseases of the intra-abdominal organs, he treats of those cases in which the condition of the peritoneum itself serves as an indication for operative interference. These several conditions he classifies under three groups.

In the first group are those cases of acute septic peritonitis arising from rupture of the intestine and escape of its contents into the abdominal cavity. Here the indication is very distinct to open and cleanse the peritoneal cavity, at the same time closing the intestinal wound or stitching the gut to the external wound in such a way as to establish a temporary fecal fistula. When the rupture of the intestine has taken place without a previous wound of the abdominal parietes, the operation is rendered more difficult by reason of the trouble which is often experienced in finding the point of injury of the gut. The detection of this lesion may sometimes be facilitated by following up the hemorrhage or the clot to its highest point where this is possible.

The second series of cases comprises those in which a general septic peritonitis has followed after an operation in the abdominal cavity, undertaken for any cause. Such cases were formerly of more frequent occurrence than they are, fortunately, at the present day. In a case of this nature it would be necessary to reopen the abdominal cavity, wash the peritoneum, and provide for thorough and free drainage. The peritoneum should be repeatedly irrigated until the inflammatory process is arrested.

The third group comprises cases of so-called idiopathic or rheumatic peritonitis. Leyden proposed operation in these, and Rose performed abdominal section twice, but with fatal result. Since then, however, others have operated in cases of idiopathic peritonitis, and have saved their patients. The author believes that an operation is justifiable in such cases, as the results have shown that recovery is to be hoped for, whereas without surgical interference the disease would doubtless have gone on to a fatal issue. Nevertheless, it is not probable that the surgical, or rather the operative, treatment of simple primary peritonitis will ever, in this generation at least, find general favor among conservative practitioners.

CHARCOT ON THE DANGERS OF HYPNOTISM.

A LAW was recently passed in Italy forbidding public exhibitions of animal magnetism, mesmerism, and the like, which has given rise to considerable discussion in the lay and medical journals. Dr. Melotti wrote to Charcot for his opinion as to the justifiability of the measure, and received a reply, which is published in *La Riforma Medica*, reprobating in the strongest terms all such public exhibitions of hypnotism.

"Hypnotization," he writes, "is by no means so devoid of danger to the subjects as is generally supposed, and it is evident that it is only by careful clinical study that the indications and the contraindications for the employment of this therapeutic agent can be, with any accuracy, established. But this is not the only reason why such public exhibitions should not be permitted. The hypnotic state is nearly related to the hysterical neurosis, which, under certain circumstances, shows itself to be highly contagious." In support of this assertion, the author referred to the numerous cases of hysteria which had been observed in Milan, Turin, and elsewhere, in consequence of these popular representations of somnambulism.

Finally Professor Charcot says, "Medicine has taken possession, in the name of science and art, of hypnotism, and she demands that it shall be entirely her own, to develop and to use in the cure of disease. In this recently acquired dominion she is jealous of her rights, and wishes to reign as the absolute mistress, free from any outside interference. It is only in this way that such an agent can be made of use to mankind, and can be prevented from working injury to the human race."

THE NATURE OF FEVER.

IN the four-fold definition which the old writers gave for inflammation, "calor" occupied a prominent place. By mere tactile sensation they were able to make a rough estimate of the amount of bodily heat. Some of them

became very exact, even by this crude method. The introduction of the clinical thermometer placed the relations of body temperature to disease on a scientific foundation, and those of us whose years of practice are few can scarcely imagine a time when it was unknown.

It has remained for later years, however, to exhume many of the questions which were presumably settled decades ago. One of the questions discusses the essential nature of that condition which we call fever. It is not a final settlement of the case when we say that a patient has a temperature of so many degrees. Such a use of the thermometer is merely empirical. There is a constant access of heat to the body from various processes which go on within it. There is a constant loss by various channels. The condition at any time is the balance between these two opposing functions. We should be able to gain an accurate idea of the relations which these two functions are bearing to each other in each individual case. That the themometer does not tell us.

The discussion on this topic has received a new impetus from the recent Gulstonian lectures by Dr. MacAlister. It has been heretofore considered that the motor and heat-making functions were in very close relationship. We have come to learn, however, that this relationship may be profoundly modified in the living organism. The motor function may persist while the thermogenic or heat-making function may be in abeyance. The latter is now regarded as being directly under the control of the nervous system—so far at least as its regulation and distribution are concerned. "Wherever," says Foster, "metabolism of tissue is going on, heat is being set free." It is not a new idea that the nervous system controls this important function. Positive evidence, however, has been slow in accumulating. Half a century ago Brodie called attention to the fact that the temperature rose after injuries to the spinal cord. Tscheschichin noticed that in rabbits after section of the cord a fall of temperature occurred, but that a section carried through the line of junction of the medulla with the pons caused a marked rise. The latter fact suggested a "heat centre" in the higher nervous structures.

Dr. MacAlister regards the heat of the body as coming from a substance—thermogen. Stimulation of certain nerves connected with the centre gives rise to its destruction. This metabolism liberates heat, and these nerves are called catabolic. Stimulation of other nerves (anabolic) causes a reformation or restoration of this thermogen. There is a close relation between the heat-centre and the motor-area. This correspondence is what we might naturally expect in view of the association of motor activity with the heat formation. The exact location of the heat-centre we are not sure of. Sachs and Aronsohn found that stimulation on the inner side of the corpus striatum caused a rise in temperature.

There are therefore three different factors in any given temperature in the body—the heat-forming, the heat-losing, and the heat-adjusting or, as Dr. MacAlister says, thermogenetic, thermolytic, and thermotaxic. Combinations of these in varying intensity may give febrile symptoms without noticeable temperature, as in mania, and we may also have temperature without marked febrile symptoms. In cold-blooded animals the thermolytic function is the most prominent. In infants, with their characteristic unstable temperature, the thermolytic and the thermogenetic are both in action. In adults both exist, and in addition the thermotaxic. In the onset of any systemic fever the latter first becomes affected, next the thermogenetic, and finally the thermolytic. In convalescence the order is exactly reversed.

From this brief allusion to these important lectures it is evident that we have come to a new era in the study of body temperature, both in health and disease. The complexity of this and similar problems seems often to increase the farther we go. We are, however, bringing into acceptance theories which more and more explain observed phenomena, and therefore constantly approximating toward the ultimate truth.

News of the Week.

A Hard State in which to Practise.—Virginia is a State which quacks and the uneducated medical aspirant are likely to shun. At the last meeting of its Board of Examiners nineteen persons applied for licenses, and only seven passed the required examination. This is a severe, but we fear a just, commentary on the slovenly methods of teaching and the laxity of final examinations in many of our medical colleges. The *Virginia Medical Monthly* says: "The object of this Virginia Board is to test candidates for practice in Virginia only upon their merits as brought out by examinations. No college professor is on the Board. The Board stands as a higher court than the college faculties; it has to pass upon the work done by the colleges. Fortunately for Virginia, the Board is composed of men well qualified for the discharge of this duty. The standard of graduation claimed by most of the reputable colleges of the country is seventy-five per cent. The Virginia Board of Medical Examiners adopts the same standard, and tests applicants solely by this standard."

Medical Degrees for Women in Australia.—At a meeting of the Council of the University of Melbourne, on February 21st, it was decided by a large majority to admit ladies as students of medicine. The principle thus indorsed is all right, but practically it has been found that the co-education of male and female medical students is often attended with considerable difficulty.

An Intercolonial Medical Congress is being organized, to include physicians of Australia and neighboring colonies. It will be held at Adelaide, South Australia, on August 30 and 31, and September 1 and 2, 1887

The California State Medical Society held its annual meeting on April 20, 21, and 22, 1887, at San Francisco.

The Medical College of Virginia at its Commencement on March 31st conferred degrees upon a class of fifteen.

The Arkansas State Medical Society meets at Little Rock on June 1, 2, and 3, 1887. The enterprising secretary, Dr. Gibson, has adopted the excellent plan of securing early pledges as to papers and attendance.

University of Maryland.—The medical department graduated a class of ninety at its Commencement on March 22d.

Dr. J. F. Huntley, of Oneida, N. Y., died on February 12th, in the sixty-third year of his age.

International Medical Congress.—Dr. J. J. Chisholm writes that "Dr. von Wecker, of Paris; Dr. Herschberg, of Berlin; Dr. Mauthner, of Vienna; and Dr. Landolt, of Paris, have accepted positions of vice-presidents in the Section of Ophthalmology. They promise to prepare papers and attend the meeting."

The American Surgical Association meets at Washington on May 11, 1887. Dr. Hunter McGuire presides, and an interesting programme has been prepared.

Society of Trained Nurses.—The Agency for Trained Nurses on Thirty-fourth Street, which has been under charge of Miss Mabie, has been given up, and the work of supplying nurses transferred to the Philomena Society, No. 1,300 Broadway. This society is composed of trained nurses, and its objects are "to cultivate the science of nursing the sick in all its branches; to advance the character and honor of the profession; to promote friendly intercourse and good feeling among its members, and to assist as far as possible members in sickness and trouble."

The Mortality in American Lying-in Hospitals.—In connection with this subject, Dr. R. C. McDonald writes that, in the Boston Lying-in Hospital, out of three hundred and seventy-three confinements there were but three deaths, a percentage of .80. None of these deaths was from sepsis.

A Journal is published in France devoted to the study of mesmeric phenomena. It is called *Revue d'Hypnotisme*. A recent number contains the description of a young woman who "beats the record" in the matter of continued somnolence, being now in her seventeenth year of uninterrupted lethargy. She is known as "The Sleeper of Thenelles."

In Prussia there are over one hundred and sixty centenarians, the oldest being one hundred and twenty years. —*Berlin Statisch. Korresp.*

Medical Missionary Work in China.—We have received the following interesting items from Dr. J. C. Thomson, of Canton, China: "'The Medical Missionary Association of China' has just been formed, with Dr. J. G. Kerr, of the Canton Hospital, as president, several sectional vice-presidents, and Dr. E. M. Griffith, of Shanghai, secretary and treasurer. Its medical journal is expected to issue its first number about the last of March, of which there are four editors, Drs. Kerr, of Canton; Gulick and Reifsnyder, of Shanghai; and McKenzie, of Tientsin. On February 15th was opened the Woman's Hospital of Miss Dr. L. H. Hoag, at Chinkiang, in the presence of the United States and British Consuls, Tartar General, and other high officials. On February 17th the 'Alice Memorial Hospital,' in memory of the English wife of Dr. Hokai, was opened for the reception of patients of all creeds and nationalities. So China moves medically."

The Brooklyn Health Board.—The Brooklyn *Eagle*, summing up the results of the Bacon investigation, says: "The Health Board is an organized brutality and imbecility."

The Seventh Annual Meeting of the Ontario Medical Association will be held at Toronto on June 8th and 9th.

Dr. Milner Fothergill, of London, will give three lectures on "The Modern Tendency of Disease" at his residence on Thursday, June 2d, 9th, and 16th, at 4 P.M. All members of the medical profession admitted on presenting their cards.

Dr. Grant Bey, of Cairo, has been made an honorary member of the Associazione dei Benemerite Italiana, and has received from the society the gold medal in recognition of his services to humanity.

The Association of Medical Editors holds its next annual meeting at Chicago, on the Monday evening preceding the meeting of the American Medical Association.

In a Case of Ovarian Tumor with ascites, occurring in a girl of twenty-two, Dr. A. G. Willey (*Cleveland Medical Gazette*) removed over half a ton of fluid (1,270 pounds) in thirty-one different operations, extending over two years. The patient weighed one hundred and ten pounds, and died after the thirty-first tapping.

Literary Piracy.—The *Provincial Medical Journal*, an alleged monthly review of medical science, published at Leicester, England, contains among its original communications an article by Dr. W. R. Whitehead on "Hip-joint Disease," with a number of cuts, all taken bodily, without credit, from The Medical Record.

Dr. Frederick M. Dearborne, Surgeon in the United States Navy, with the rank of Lieutenant-Commander, died last week. Dr. Dearborne was made Acting Assistant Surgeon August 18, 1862; Assistant Surgeon in 1864; and Passed Assistant Surgeon in 1867. In 1875 he was promoted to be Surgeon.

The London Correspondent of the New York *Times* criticises the loud tone of voice in which Americans talk, and illustrates it by the following incident: "I walked up Cheapside the other day with a young New York surgeon, just arrived, a very gentlemanly and polite man, and he explained to me as we walked some of the structural peculiarities of the eye as affected by cataract. It was not, as they say in Parliament, a contentious subject, yet my companion yelled so fiercely in explaining his meaning to me that practically everybody passing on both sides of the crowded thoroughfare turned to look at him. From time to time I hinted to him not to talk so loud. He then would moderate his voice for a sentence or so, then back it would go to a literal scream."

A New State Insane Asylum.—At date of writing, it is uncertain whether the proposed new insane asylum for Northern New York will be located at Ogdensburg or Plattsburg. It is an interesting commentary on the management of these institutions that certain politicians are quarrelling each to have the asylum in his own locality.

Cholera and the State Board of Health of Wisconsin.—The Assembly of Wisconsin has passed a bill appropriating $15,000 as a contingent fund, to be used, if necessary, in the next two years by the State Board of Health in preventing the introduction of cholera into that State.

A Physician Charged with Malpractice for Giving an ordinary Dose of Morphine.—A Richmond, Va., physician was recently arrested, charged with having caused his patient's death by giving an overdose of morphine. The physician stated that he was called to see the patient, found her in great pain, and administered, hypodermatically, a quarter of a grain of morphia; in three-quarters of an hour, finding her still unrelieved, he administered, hypodermatically, a little less than a quarter of a grain. Soon alarming symptoms set in, and in a few hours, in spite of all treatment, she died. If this is the correct account, a manifestly great injustice was done; for medical practice could hardly be pursued, if the doctor were in danger of arrest when he gave half a grain of morphine. *The Southern Clinic* says that it was in evidence before the police-court that the patient had taken a certain amount of whiskey just before the administration of the morphia. In reference to the possible action of this agent in connection with morphia, Dr. Taylor, the coroner, testified that the alcoholic stimulant was antagonistic to the action of morphia, would retard its action, etc. *The Clinic* shows the error of this view, and cites the following authorities:

"Alcoholic stimulants often seem to intensify the toxic effects of opium or morphine."—*Waring's Therapeutics*, edition of 1886.

"In the treatment of opium-poisoning be careful of *alcohol*, for fear of *deepening the narcosis*."—*U. S. Dispensatory*, edition of 1886.

"Alcoholic stimulants are used by some habitues *to increase the effect of morphia*, which it does."—*Kane's Drugs that Enslave*, edition 1881.

Cancer is increasing in Victoria, Australia, the death-rate from it being 4.58 per 10,000 in 1880–84, as against 1.91 per 10,000 in 1861–70.

Columbia College was not as generous to the profession with her honorary degrees, on the occasion of her recent anniversary celebration, as Harvard was; the only two medical men on whom such degrees were conferred being Helmholz, of Berlin, and Dr. John C. Dalton, President of the College of Physicians and Surgeons of New York.—*Boston Medical and Surgical Journal.*

Some complaints have appeared, also, because in the arrangements for the Centennial celebration the Faculty and students of the medical department were not properly supplied with tickets.

A Tumor of the Cerebellum was recently removed by Mr. Bennett May, of England. The diagnosis was correct, and the operation "successful" as an operation; but the patient, a boy of seven, died.

Antithermin is the name of the latest antipyretic agent. It is allied chemically to antipyrin, and its scientific name is phenyl-hydrazin-leonlinic acid.

State Board of Health of Nebraska.—The bill proposing a State Board of Health for Nebraska has failed to pass the legislature.

Reform in Spelling.—Professor Skeat, in a recent number of *Notes and Queries*, says: "Those who know the whole history of our spelling from the eighth century to the present time best understand the harm done by the pernicious system of trying to transplant Latin and Greek symbols into the English language. The symbols *æ* and *œ* are not English, and are best avoided. Indeed, this is done in practice when once a word becomes common. *Æther* and *æthereal* have been sensibly replaced by *ether* and *ethereal*. No one now writes *æternal*. *Solœcism* is now *solecism*, and I trust that *primeval* and *medieval* will soon prevail over *primæval* and *mediæval*. Pedantic spellings are most objectionable, because they are useless and unphonetic." To this the *British Medical Journal* adds: "We heartily agree with Professor Skeat, and trust that *diarrhœa*, *leucorrhœa*, *dysmenorrhœa*, etc., will soon give place to *diarrhea*, *leucorrhea*, *dysmenorrhea*, etc." We can ourselves add a little illustration of some peculiari ies in medical orthography:

A man once caught typical phthisis
By being exposed to the bhrhisis;
So he, cold death to foil,
Took some cod-liver oil,
Which instantly brought on emhisis.

If such an illustration is insufficient, a study of any medical dictionary justifies the following:

A young man with a very marked ptosis,
Once met a sweet girl who sold prosis,
Said she, "Will you try
Some flowers for your eye?"
But he answered her pleasantly, "Pno, sis."

Investigating Leprosy in America.—The Norwegian Government has taken another step toward discovering the origin and nature of leprosy, which is so common on the west coast of Norway, by despatching Dr. G. A. Hansen, Director of the Leprosy Hospital at Bergen, to North America, for the purpose of inquiring into the heredity of the disease among Scandinavian emigrants to the United States.

Medical Work is closely allied with charitable work, and physicians will be both interested and profited by a knowledge of the results of the investigations of charity organization societies obtained in Boston and New York. These show that in large cities the proportions of worthy and unworthy applicants for relief is very nearly a fixed one, and that a general law can be laid down, which is as follows: Among one hundred applicants for charity there will be found nine worthy of continuous relief; twenty-two worthy of temporary relief; fifty-four needing work more than relief; fifteen unworthy of relief; this is the result of an investigation of 16,496 cases.

Phaseoli Vulgares, as they say in Boston, or baked beans, is the subject of a learned essay by Dr. Ephraim Cutter in the *Albany Medical Annals*. Dr. Cutter finds that baked beans are indigestible because the starch-granules are enclosed in an adamantine coat of cellulose, which is not destroyed by cooking. When properly cooked, however, the bean is a very nutritious food. Dr. Cutter, without intention, does not do the bean full justice, for he leaves it to be inferred that the chief nutritive ingredient is starch, whereas it really has a larger amount proportionately of nitrogeneous matter (legumine) than other vegetables. White beans contain 55 parts of starch, + 25 parts legumine, fat 2.8, giving a nutritive ratio of 1 to + 2, or about the same as that in perfect and normal food milk.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 21, 1887.

A. Jacobi, M.D., President, in the Chair.

THE PRACTICAL VALUE OF OUR PRESENT METHODS OF TREATING THE UPPER AIR-PASSAGES.

The Section on Laryngology and Rhinology presented the above subject for discussion, and papers were read by Drs. F. H. Bosworth, Andrew H. Smith, W. H. Thomson, H. Holbrook Curtis, and W. C. Jarvis (see pp. 487–495).

The President acknowledged the donation to the Academy, by Dr. Andrew H. Smith, of

AN AUTOGRAPH LETTER OF RUDOLPH VIRCHOW,

written in 1866, and containing a biographical sketch of himself.

A like presentation had been made to the Academy by Dr. Allan McLane Hamilton, consisting of a manuscript in the handwriting of

JULIEN BOUVIER,

who was practising in New York in 1796. The letter was dated August 4th of that year, and was addressed to Alexander Hamilton, Secretary of the Treasury of the United States. The subject was *A Medical Inquiry into the Use of Cold Water in Malignant Fevers, especially Yellow Fever.*

The President also contributed a manuscript by

ERNST KRACKOWIZER,

with reference to the reorganization of Bellevue Hospital in 1874.

He then spoke of the great value of a large collection of similar manuscripts, a gathering which would finally become invaluable on account of their rarity and intrinsic worth. He asked as a favor to the Academy that such manuscripts be presented to the Library.

The Academy then adjourned.

SECTION IN PRACTICE.

Stated Meeting, April 19, 1887.

E. Darwin Hudson, M.D., Chairman.

Dr. Andrew H. Smith read a paper on the

SYMPTOMS, PATHOLOGY, AND DIAGNOSIS OF ACUTE OPIUM-POISONING,

in which he confined himself to the consideration of the grade of opium-poisoning which threatens the life of the patient, or causes solicitude to the practitioner. The *symptoms* are generally so distinctive as to leave but little room for error. The intellect is usually almost wholly dormant. The patient may be aroused, but immediately passes into his former condition. In a few cases active delirium occurs. One of the most constant symptoms of opium narcosis is *contraction of the pupil.* Contraction of the pupil, however, should not be allowed too great weight in diagnosis. Unless other symptoms point to a like conclusion it should not be accepted as indicating opium-poisoning, and it must also be borne in mind that as death is approaching the pupils become generally widely dilated.

The *respiration* is very commonly reduced in frequency. The most dangerous narcotism, however, may be developed while the respiration is

AT OR NEAR THE NORMAL FIGURE.

Doubtless, if the rate of respiration were always noted in reports of cases of opium-poisoning, such cases would not be very rare. Dr. Smith thought that this fact was first brought to the notice of the profession in a paper which he read before the Medical Journal Association in New York in 1875. The fact that such cases may occur renders it extremely important that absolute reliance should not be placed upon the respiration to sound the note of warning as danger approaches in the plan of treatment of certain diseases of which opium plays a prominent part. The contraction of the pupil and the effect upon the intellect will serve to put the practitioner upon his guard.

After referring to the *post-mortem* appearances, in which there are no specific lesions, and also to the pathology of opium-poisoning, Dr. Smith passed to the question of *diagnosis*, where he gave the differential points between

OPIUM-POISONING AND APOPLEXY,

such as inequality of the pupils in the latter and equal contraction (as a rule) in the former; inability to rouse the patient in the latter with ability to excite reflex movements, while in the former reflex movements cannot be induced, although the patient can be momentarily aroused; evidence of hemiplegia in the latter which are absent in the former, etc.

Uræmic coma lacks the characteristic pupil of opium-poisoning, and in *alcoholic* intoxication the pupils are not contracted.

The *prognosis* in opium-poisoning is extremely favorable if efficient treatment is employed. Persons have been rescued after the respiration had fallen as low as one in two minutes. Persons have recovered after taking five, six, and even eight ounces of laudanum. While, therefore, a sign of life remains, efforts at resuscitation should not be relaxed.

It is well known that in cases of *defective elimination by the kidneys* opium may cause dangerous or even fatal narcotism, when given in doses that would be considered trivial under normal conditions. The danger of using morphine when the system is under the influence of chloral, should also always be borne in mind.

The *treatment* may be considered under the following heads:

1. Evacuation of the stomach. (Tartar emetic should never be used, and ipecac acts too slowly.)
2. Administration of certain drugs, which are in some degree antagonistic to opium. (Nitrite of amyl, oxygen, coffee, and belladonna.)
3. Efforts to arouse the nervous system. (Flagellation, but not bruising; walking the patient; dashing cold and hot water alternately over the head and face; faradism, touching the tip of the nose or the rim of the ear.
4. Efforts to maintain respiration. (Artificial respiration, electricity applied to the phrenics in the neck, etc.)
5. Efforts to keep up the circulation and temperature. In connection with this point he referred to a paper by the late Dr. Gaspar Griswold, who showed that, in using electricity to stimulate the heart's action,

EXCESSIVE STIMULATION OF THE PNEUMOGASTRICS

tended to arrest cardiac action.

The withdrawal of a pint or more of blood from the veins and its replacement by a similar quantity of either milk or a saline solution, would be a rational method of getting rid of a portion of the poison circulating in the vessels, but Dr. Smith could not see any utility in adding a pint of milk to the undiminished bulk of the blood, as was unsuccessfully done by Dr. Gilliam, of Columbus, O., in a case reported by him a year or two ago in a St. Louis Journal.

Dr. W. H. Thomson spoke of the importance of recognizing the condition present, after the diagnosis had been made of opium-poisoning. He thought that the routine treatment was frequently to the detriment of these unfortunates, simply because what were supposed to be antidotes were remembered.

NEUROTICS HAVE NO ANTIDOTES.

All that could be expected, therefore, was that certain dangerous effects might be counteracted by the action of neurotics, to a certain limited degree and no more.

Probably no two cases of opium-poisoning were alike, nor would they be alike in the same person at different times. The same was true of chloroform. A woman with peritonitis bore chloroform badly; but in parturition she bore it almost without danger; while the same person in the dentist's chair might succumb instantly to the influence of the drug.

When called to a case of opium-poisoning, therefore, the exact condition of the patient should be studied with special reference to whether that condition could be counteracted by this measure, or that. He would look for indications somewhat as follows:

Are the cardiac stimulating effects of the drug still present or not? If the pulse was full and strong the patient was quite certain to recover. But in many patients depression of the heart, present previous to the taking of the opium, does not allow the drug to exercise its stimulating effect, and there is a weak pulse, and the indication then is for *the immediate use* of nitrite of amyl, nitro-glycerine, and oxygen, and with these belladonna. In one case he gave *twenty* drops of the tincture of belladonna every fifteen or twenty minutes until *four* drachms had been taken, and with marked benefit. He prefers the belladonna to hypodermatic injections of atropia.

But the cases which are dangerous are those in which belladonna is useless, if not injurious. The pulse has lost its strength, respiration is shallow, change cannot be produced in the pupil, the surface is cold and pale, and the perspiration is cold. In these cases do not try belladonna. Nor did he like to overstimulate with caffeine, for caffeine in large doses depresses respiration. In such cases, then, nitro-glycerine and nitrite of amyl were indicated, and also electricity.

But he would

WARN AGAINST THE USE OF ELECTRICITY

about the nostrils or throat, because all applications of that kind, including ammonia, to these parts slowed the respiration in health. On the other hand, the surface of the chest down to below the diaphragm should be faradized. One pole may be placed upon the nape of the neck, and the other passed over the precordia and down over the region of the diaphragm.

Dr. Beverley Robinson reported a case occurring in St. Luke's Hospital, in which there was generalized pulmonary emphysema, chronic bronchitis, enlarged heart, acute mania, and morphine-poisoning. The last-mentioned condition was treated with injections of atropine, artificial respiration, black coffee, the faradic current, and inhalations of oxygen. The patient was a man, sixty-eight years of age, and the case terminated fatally. The patient was also seen by Drs. Andrew H. Smith and James R. Leaming. After giving a detailed history of the case, Dr. Robinson made the following remarks:

"In reviewing this case I would add merely that it appeared to me, at the time, the patient was evidently suffering from the effects of an over-dose of morphine, and that he received as much benefit in starting the respiratory movements from

ARTIFICIAL RESPIRATION

as from the intelligent use of the faradic current. The battery employed was the small portable one of Gaiffe, in which the bisulphate of mercury is used as a chemical agent to start the current. An important observation of Dr. Smith's and of myself was that one pole of the battery could be employed with equal efficiency and less danger over the lower jaw and lobule of the ear than over the side of the neck, where the pneumogastric might be unduly stimulated, and thus, perhaps, occasion the sudden and complete arrest of the heart's action. This seems to be in accord with the conclusion arrived at by the late Dr. Gaspar Griswold, with respect to the use of electricity in morphine poisoning, who states (The Medical Record, February 28, 1885, p. 245) 'that under no circumstances should an electrical current, sufficiently strong to produce contractions of the muscles in any part of the body, be applied over the phrenic or pneumogastric in the neck.' It is also in accord with his statement (*Ibid.*, p. 246) that he would, under analogous conditions with those mentioned in the history of my case, rely more upon artificial respiration than upon electricity; in fact, this distinguished young observer remarks that in those cases 'in which morphine had entered a vein he would not use electricity at all.' That electricity may be applied, however, in these cases so as to stimulate respiration, and without at the same time occasioning any dangerous depressing effect, is obviously proven by the wise use made of the faradic current in the hands of Dr. A. H. Smith. I would also mention that even after the hypodermatic injection of one twenty-fourth of a grain of atropine, in all, there was no dilatation of the contracted pupils. Was our case one of those which succumb to the *secondary exhaustion* brought on by an an overdose of morphine? I scarcely believe so in view of the other complicating affections from which my patient previously suffered."

Dr. F. A. Castle spoke of the importance of estimat- the condition of the patient in each individual case. A considerable number of cases occur accidentally in those who are the subjects of chronic alcoholism. This class of cases give poor results from treatment. In suicidal cases the persons for the most part have as previous conditions, due to various causes, fatty hearts or disease of the lungs, with limited respiratory power, and in such cases the chances of recovery are comparatively small, and in proportion to the damage they have received from other poisons or previous diseases.

In persons who are not suffering from chronic alcoholism, etc., the chances of recovery are much better. But besides these, there are certain other conditions which require careful consideration, as already stated by Dr. Thomson, before resorting to

THE ROUTINE PLAN OF TREATMENT.

He believed that considerable caution should be enjoined in the use of atropine, lest thereby another source of danger was given to the patient.

Dr. H. B. Millard then read a paper [see p. 484] on

THE BEST TESTS FOR ALBUMIN,

with practical remarks relating to urinary examinations.

Dr. W. Mendelson had devoted much time to the making of urinalyses, and had reached the conclusion for himself that the method of boiling and then adding acid was relatively the best test for albumin that could be used. His method was to boil the upper portion of the urine in the test-tube, and then add a drop of acetic or dilute nitric acid. He regarded it as important to first boil the urine and then add the acid. By this method an excess of nitric acid would not dissolve the albumin. The substance most liable to be mistaken for albumin was mucin. He believed it to be doubtful whether exceedingly small traces of albumin were pathological. A point which he obtained from Dr. John G. Curtis, and which he looked upon as a valuable one, was the fact that albumin was generated in urine by the death of bacteria. In all cases where only very slight traces of albumin or of doubtful substance can be found, a microscopical examination of the urine should be made, and may materially aid in deciding whether or not

ALBUMIN IS PRESENT.

Dr. Charles A. Doremus said it was important to *first* ascertain the reaction of urine submitted for examination. In the second place, the urine should be perfectly clear; and to accomplish this precipitation was preferable to filtration. He believed it to be wise to use a corroborative test, whichever of the numerous tests might be adopted. The ferrocyanide test, it properly applied, he regarded as sufficiently accurate. Heat was a delicate test, but it was very apt to be used too hurriedly. The nitric acid, also, was extremely delicate.

Dr. George B. Fowler also spoke of the great importance of first ascertaining the reaction of the urine, and he indorsed the method mentioned by Dr. Mendelson, namely

BOILING FIRST AND THEN ADDING A DROP OF ACETIC OR ANY OTHER DILUTE ACID.

Heat does not precipitate albumin in alkaline urine, and too much acid will give the same result. Alcohol would clear up certain precipitations, with watery solutions, but in urine it would not answer. The best method he had employed for *filtering* urine was through thoroughly washed sand.

Dr. W. M. Carpenter doubted if such slight traces of albumin in urine as four one thousandths of one per cent. had a special clinical significance in the midst of so many external influences—and also internal, independent of renal disorders—that give rise to the transient presence of small quantities of albumin in the urine. At the same time, it was a wise precaution to keep such cases under observation. As to bacteria developing albumin, he had always declined to give an opinion concerning the presence of either albumin or casts when the urine was well charged with bacteria, and asked for another specimen. Urine that contains casts may become

FREED FROM CASTS AS BACTERIA MULTIPLY.

Heat and nitric acid were the tests for albumin on which he had relied.

Dr. Robert J. Devlin mentioned a filter which he had prepared by pouring upon it a freshly made precipitate of magnesia, obtained from dilute solutions, so that it may be as finely divided as possible. When the filter is thus coated with a thin gelatinous deposit, carefully add the urine—either the entire sample or the lower stratum simply, in such a way as to disturb the film on the paper as little as possible. Then scrape off the entire deposit while moist, and mingle in a test-tube with sufficient very dilute nitric acid to clear up the magnesia. The organized deposits can thus be obtained in a very concentrated condition for microscopical examination.

Dr. A. H. Smith had had satisfactory results from the use of picric and citric acids.

Dr. W. G. Thompson thought that the most accurate and delicate test was one which could be most easily applied, and that was boiling the urine first and acidulating it afterward. He preferred reflected to transmitted light in examining the specimen while the test was being applied.

Dr. F. J. Bowles had found that nitric acid would in some instances precipitate albumin when heat and nitric acid would not.

Dr. Fowler remarked that there were specimens which yielded a precipitate to nitric acid, but would not to heat, and *vice versa*, so that in each instance both heat and nitric acid were the most delicate respectively.

The Chairman asked if granular casts had been found in the urine without albumin being present at any time.

Dr. B. Robinson had seen kidneys that were the seat of chronic diffuse nephritis, in which repeated examinations detected both albumin and casts, and afterward neither the one nor the other.

Dr. Millard had met with a number of instances where albumin had been absent, and yet granular casts were found, and he believed that albumin might appear in the urine without disturbance of the uriniferous tubules. He had long since discarded the picric-acid test. Peptones and protein bodies would not always disappear under heat. Heat and nitric acid were very delicate tests for chemists, but he thought that they were less likely to prove so for the general practitioner. Heat was the most available of all tests, doubtless, if all precautions were observed. That casts would disappear when bacteria were present was a new point to him.

The Section then adjourned.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, March 1, 1887.

Charles L. Dana, M.D., President, in the Chair.

Dr. H. M. Biggs reported a case of

ALCOHOLIC PARALYSIS DUE TO MULTIPLE NEURITIS.

The patient was a married woman, twenty-five years of age, who had been a moderate drinker. About six weeks before death she began to have pains in her legs, followed by weakness, and she rapidly developed a painful, wasting paralysis, involving the legs chiefly and the arms slightly. In the lower extremities there were hyperæsthesia, paræsthesia, and reaction of degeneration over affected muscles. The extensors were most involved. There was no implication of the bladder or rectum. The temperature on admission to the hospital was 100° F. The woman died of intercurrent pleurisy.

Autopsy.—Patient greatly emaciated. Legs and thighs markedly flexed. Muscles of the legs of a yellow color, and apparently converted almost entirely into fat. Muscles of thigh much less affected. Spinal cord and nerve-roots and -trunks normal in appearance.

Microscopical appearances.—Spinal cord apparently normal, with the exception of slight sclerosis in the columns of Goll in the cervical region. Nerve-roots normal. In one of the sacral nerves before its exit from the spinal canal was found a marked increase in the endoneurium, with diminution in the number of the nerve-fibres, and an irregularity and indistinctness in these appearances. The right sciatic nerve showed the same changes more marked. In the posterior tibial nerve the process was even more advanced, and in this only an occasional nerve-fibre could be detected. Microscopically, the gastrocnemius was composed almost entirely of adipose tissue; only here and there atrophied muscle-fibres were found. The small nerve-trunks in the muscle showed advanced degenerative neuritis, with comparatively little new growth of connective tissue in the nerves.

The President thought that in this case it had been fully demonstrated that the alcoholic paralysis was due to a neuritis, and not to a myelitis. This was the first case with autopsy presented in this country.

Dr. M. A. Starr had seen the specimens, and said there was no question with regard to the existence of neuritis, in this case, and the normal condition of the anterior cells of the spinal cord. There was slight sclerosis in the columns of Goll, which he was unable to explain. The same condition had been observed in a case of Hamilton's recorded by Granger Stewart.

Dr. Biggs said that, contrary to the ordinary condition found, the process seemed to be more a degeneration of nerve-fibre than an interstitial neuritis, especially in the smaller nerves.

Dr. Noyes spoke of the frequent occurrence of amblyopia with alcoholism, and said it was due to a partial neuritis of the optic nerve, referred, as had been shown, to the centre field, and not to the field at large. He suggested that in cases like the one reported by Dr. Biggs the neurologists should make careful examination of the optic nerves. In reply to Dr. Starr, whether scotoma was due as frequently to tobacco as alcohol, he said it might be due to either, but the patients frequently combined the two habits.

The President said the name alcoholic paralysis was in some cases rather begging the question; this patient, it seemed, had been only a moderate drinker. He had observed other cases in which the alcoholic element was small.

ABSTRACT OF DR. STEVENS' PAPER ON IRRITATIONS ARISING FROM THE VISUAL APPARATUS CONSIDERED AS ELEMENTS IN THE GENESIS OF NEUROSES.

Two classes of influences were recognized as causes of functional nervous disorders—the remote and the im-

mediate. The remote causes may be sufficient to perpetuate a neurosis when once a nervous irritation has been instituted. While immediate causes rarely induce long-continued disorders, a pre-existing influence may serve to continue it indefinitely. It is of little practical importance that some exciting circumstance has given rise to a nervous trouble. The event has passed and cannot be recalled. If there is an underlying cause it is of much more importance.

Persons in whom underlying causes of a neurosis exist are said to possess a neuropathic predisposition, and those subject to it are liable, from trifling immediate causes, to suffer from various neuroses. In a considerable proportion of cases the neuropathic tendency is hereditary; but the result is not always manifested in the same form in different generations.

A third class of cases which should be recognized may be designated as *modifying tendencies*, among which may be mentioned vitiated atmosphere, the period of life, and the performance of certain physiological functions.

Often, as a result of the predisposing influence, when one form of complaint is supposed to be cured, the subject of it is simply suffering from some other form.

Must the predisposing cause of neurosis be general, pervading the whole organism, or must it of necessity be located in the great nerve-centres, or may it be entirely local and outside those great centres? Undoubtedly it may be local, and confined to any portion of the nervous system.

Inasmuch as the tendency is often hereditary, may not the evil consist of some peculiarity of anatomical structure or of physiological adaptations which are inconsistent with the most regular and easy performance of the function of a part or parts, and may not certain classes of mechanical peculiarities be unusually liable to become factors of physiological disturbance?

If we answer in the affirmative we assume a hypothesis which must be maintained by long-continued observations, conducted in a spirit of judicial independence, and free from the bias which might result from occasional and exceptional experiences. The conclusions announced this evening are based upon observations in more than five thousand cases in private practice, and of a considerable number in public institutions, all of which have been made with as much precision as the exacting demands of an active professional life would permit. The central truth, as arrived at by these observations, may be stated as it has already been done in a memoir to the Royal Academy of Medicine of Belgium, in 1883, as follows:

"Difficulties attending the functions of accommodating and of adjusting the eyes in the act of vision, or irritations arising from the nerves involved in these processes, are among the most prolific sources of nervous disturbances, and, more frequently than other conditions, constitute a neuropathic tendency."

In the proposition all causes of nervous irritation are recognized. It is held that the influences indicated are pre-eminent, but not exclusively permanent causes. Let it be remembered that it has been universally conceded that the nature of the neuropathic tendency is unknown. If one pre-eminently important element is demonstrated, it is not to be rejected because it may not include the whole.

The speaker proposed only to illustrate the result of his experience by exhibiting some photographs of cases of notable neuroses which showed very remarkable changes of physiognomy, such as habitually occurred when certain hurtful tensions of the ocular muscles were relieved. If he had designed to present only the most remarkable cases of the class to which these belonged, he should have chosen only a few of them. The design was, however, only to show by these contrasting photographs the very notable improvement which, in obstinate, and by ordinary means hopeless, cases of the most important neuroses, might be expected from relief from certain hurtful tensions of the eye-muscles.

The portraits were in pairs, the first having been taken at the commencement of treatment, the second at a later period—the interval being, on an average, about one month. The first series represented cases in his private practice; the second series, cases which were under his care for a short time, at the Willard Asylum for the Insane, last summer. The first series had been made by various photographers; the second, by Dr. P. U. Wise, Superintendent of the Willard Asylum. Thirteen pairs of photographs were exhibited—nine of the first and four of the second series. In all these, very striking contrasts existed between the first and second portraits.

In No. 1, a weary and listless young girl, a sufferer from headache, and who had never been able to attend school, is seen to be transformed, in twelve days, into a vivacious and thoroughly awake child, following relaxation of each of the inner eye-muscles. The change in health was marvellous. In No. 2, an epileptic girl, whose vacant gaze and half-open mouth indicated a profound degree of dementia, within a single month put on an appearance of robust health and of lively intelligence. In another case, a boy, choreic from infancy, and imbecile, whose constant movements were too rapid even for the modern photographer, showed, in the second photograph, from which the distortions of the face and wrinkles in the skin had disappeared, a clever mental state.

The speaker related in brief some of the results of a short season among the most hopeless cases of the Willard Asylum for

THE INSANE.

Two of these hopeless cases, who had during the month preceding treatment directed to the eye-muscles been subjected to about one hundred and seventy convulsions, suffered only about forty convulsions in the month succeeding that treatment, notwithstanding the withdrawal of all bromides.

FIFTY PER CENT. OF EPILEPTICS

so treated had remained well for a length of time varying from many years to only a single year, but sufficiently long to indicate that a great change had been wrought. Thirty-two per cent. had received very marked relief, but little short of absolute cessation of the complaint. They were all better without drugs than they had formerly been with. In seventeen per cent. no good results had been obtained.

The speaker thought that, with a better understanding on his own part of the extremely complicated conditions of the ocular muscles often found in epilepsy, this record could be improved.

The methods of procedure in examining for muscular defects was given. It differed radically from that proposed by Graefe and generally adopted, and from other methods which had been suggested. His method of performing tenotomy was also described.

Dr. E. C. Seguin said, with regard to the etiology of neuroses and serious mental disorders, that he thought we ought to look a great deal deeper than the exciting and superficial causes which occurred in many cases of that kind. In epilepsy and chorea, for instance, he thought we had to look for the efficient cause, not in disturbed external apparatus, but to hereditary predispositions and faulty tendencies. That faulty external apparatus would cause more attacks, or possibly aggravate the mental disorder, he thought no one would deny; consequently the optic apparatus, the genital apparatus, etc., should be put in perfect order. As to the great improvement after tenotomy in epilepsy, the records of surgery and medicine were filled with cases in which trauma of various kinds had interfered with epileptic manifestations for months, or even years. It seemed to him the report of a case within six months after tenotomy was rather premature. He referred to one of his cases of epilepsy,

recently submitted to division of the ocular muscles, the bromides at the same time being withdrawn, and three days later she commenced to have from six to twelve convulsions in the twenty-four hours—more than she had ever had before the operation. He had had patients go three years without an epileptic attack, and then have a relapse.

Dr. H. D. Noyes thought the precise ocular conditions in the cases reported should have been recorded; perhaps they were in that part of the paper not read. He had with him exact records of a number of cases of ocular trouble, with the result of treatment. It had not fallen within his experience to meet with the class of cases referred to by Dr. Stevens. He dwelt upon the importance of making a thorough ocular examination, including that of the muscles of the eye, in every case. He had come to realize more and more the importance of insufficiency of the external recti. He had obtained benefit in many cases from prisms. He spoke of the method of examination and of performing tenotomy. The paper deserved the most careful consideration.

Dr. D. B. St. John Roosa said that the real point in the paper was, he thought, that the correction of errors of refraction, improper relation between the ciliary and internal recti muscles, and other deviations of the ocular muscles, was capable of curing constitutional disease. He took it that epilepsy was a constitutional disease, and not merely a functional disturbance. The same was true of chorea. The question was, Did these operations cure epilepsy and chorea? But it had been shown that people with chorea got well without ever having errors of refraction corrected. It had also been shown that the vast majority of people who were not myopes were hypermetropics, yet suffered no inconvenience from it. In this the author's second paper another step had been taken—namely, that these constitutional diseases, epilepsy and chorea, were due, not solely to errors of refraction, but to want of co-ordination between the recti and ciliary muscles. Then the prism-test came upon the field, and we had to exercise the ocular muscles by prisms. Then in the order of advance came the doctrines taught in the paper of to-night. Granting the claims of the paper, that the patients had for a time after correction of an ocular difficulty been greatly relieved, possibly cured, yet that was a long way from assuming that the ocular disturbance, whatever it was, was the cause of the epilepsy. Many great men having strabismus had not become choreic, epileptic, nor insane.

Dr. A. L. Ranney thought that, following the exhibition of the photographs, little need be said in confirmation of the views advanced by Dr. Stevens. The photographs were so startling that they would be accepted in any court of justice by an unprejudiced jury as proof that unmistakable benefits had been derived from the treatment. He had personally seen and examined several of the cases, and he considered the published histories as decidedly underestimated. Dr. Ranney had performed the operation for the relief of ocular insufficiency nearly two hundred times, and had carefully examined the condition of refraction and accommodation, as well as that of the ocular muscles, in several hundred subjects afflicted with various forms of nervous disease. He did not pretend to pose as an oculist, but as a neurologist. Originally he was a sceptic, but his scepticism became no longer tenable when he saw a choreic and epileptic imbecile, in Dr. Stevens' office, who was perfectly restored in a short time to health and mental sanity by the method he had described. He thought the paper would tend to establish a new era in neurology. Regarding the operation, in no case had he had bad effects from it, but the treatment required careful regard to detail.

Respecting the view that the eye is an important factor in creating and prolonging the so-called "neuropathic predisposition," the following facts were pertinent: 1. No one has yet shown in what this predisposition lies; hence, if Dr. Stevens has shown that eye-defect is an important element in these conditions a great advance has been made. 2. There is no recognized pathology in functional nervous diseases. 3. Heredity is very common in these affections. 4. My records, in common with those of Dr. Stevens, go to show that eye-defect is found in a very large proportion of such subjects. 5. Many of the eye-defects found can be shown to be congenital, being inherited like feature. 6. The manifestations of the neuropathic predisposition vary with each case, and are called forth often by trivial circumstances which are too frequently regarded as of great clinical interest.

In the treatment of the severer forms of functional nervous disease—for example, in chronic epilepsy—one radical cure without the aid of drugs offsets a thousand failures as a proof of the scientific value of a discovery. Dr. Stevens had seven cases free from epileptic seizures for more than five years after tenotomy of the eye muscles, and without the aid of drugs. This could not be explained by chance. Then the records of the Willard Asylum were hard to contradict.

During the past year and a half he had seen sixteen epileptics in private practice; in only one was no defect in the eye-muscles found. He had an opportunity to operate on the eyes in eight of the cases—three of these were cured; two had had no fits for over a year; in the five cases still under observation the attacks had been lessened in all, drugs having been withdrawn. One had been reported by Dr. Stevens. In headache and neuralgia he had had some very remarkable results from tenotomy of the eye-muscles; also satisfactory results in hysteria and hystero-epilepsy.

Dr. Hermann Knapp said his practice had not brought him much in contact with people who had neurotic conditions, and most of those whom he had seen had passed into other hands. He was very much surprised to learn that there was so high a percentage of ocular difficulties in the patients Dr. Stevens examined in the asylum. He thought nervous people generally showed not only one complaint. Many people, especially young ladies, who suffer from headache, etc., cease to complain after correction of a deviation of the eye-muscles, etc. He had listened with the greatest attention to Dr. Stevens, and he felt quite sure that his work was not only legitimate, but that it was highly promising. He was only afraid we would not be spared disappointments in that line of treatment.

Dr. Gruening said his experience had been very much like that of Dr. Knapp. He always examined for muscular defect, and said that when one placed a prism before the eye it disturbed binocular vision. For the correction of this apparent muscular defect an operation was performed, but the muscle was sewed to its original place, or the lateral attachment was not divided; and this was only the simulation of an operation. He had benefited many patients by cylinders.

Dr. Stevens, in closing the discussion, said there was no suggestion in the paper regarding cures. He did not believe in cures. Take away the cause of the trouble and they got well. If the patients could not be said to be cured, it was still a very fortunate thing that they had got rid of their chorea, epilepsy, etc.

Bicarbonate of Sodium in the Treatment of Gonorrhœa.—It is now generally admitted that gonorrhœa is a parasitic affection. Observation seems to prove that the parasite can only exist in an acid medium, and the injection of non-irritant alkalies naturally suggests itself. Before commencing treatment, Dr. Costellan ascertains by means of litmus paper the acidity of the pus—a sure indication of the nature of the affection. He uses a one per cent. solution of bicarbonate of sodium, to be injected three or four times daily. From seven to eight days' treatment is generally sufficient to procure a marked diminution in the quantity of discharge, and convalescence is rapid. The injections at once relieve the scalding which accompanies micturition.—*The London Medical Record.*

Correspondence.

LOCAL TREATMENT OF DIPHTHERIA.

A Note from Professor J. Lewis Smith.

To the Editor of The Medical Record.

Sir: When Dr. Jacobi writes on diphtheria, as indeed on any other subject, his remarks extend our knowledge and abundantly repay perusal. I read with great satisfaction his recent paper on diphtheria, until I came to the sentence recommending emetics, and especially the following sentence: "When Dr. J. L. Smith quoted me as having advised the inunction of mercurial ointment into the region of the larynx, he mistook my meaning." I am sorry that one who has contributed so much to pædiatric literature should find his views on diphtheria quoted wrongly. I cannot now remember in which journal I saw his remarks, which I looked over more than once. I will endeavor to find them when time permits. The mistake may have been with the reporter, who, at the society meetings, if there happen to be any unusual noise, as by the entrance of members, does not always catch the meaning. The late Dr. Peaslee, who will long be remembered in New York for his interesting, instructive, and pertinent remarks at our evening meetings, once said to the writer that he took little pleasure in seeing his opinions in print, on account of errors made by reporters. But he excepted in his general condemnation of reporters the one who has since, in the editorial chair, raised The Record to its present high position among the journals of this country. So Dr. Jacobi's wrongly understood remarks were probably not seen in The Record.

It was certainly gratifying to physicians, who wish to extend and establish in this country the best possible treatment of diphtheria, to observe how, at the recent discussion, with one exception, mild and unirritating, but frequent and efficient antiseptic applications to the local disease were recommended. Did I not know that the columns of The Record are overcrowded, and much matter excluded through want of space, I would be glad to extend my remarks. But allow me one word in reference to the instruments used for local treatment. Those most frequently used are the bulb with stem attached, the small syringe, glass or gutta-percha, various forms of atomizers, the probang, and camel-hair pencil. I will state my experiences with these instruments. In treating the nostrils we all agree that the solution should be used warm and as often as every second hour, if there be evidence of a nasal pseudo-membrane. The mixture employed should be antiseptic and non-irritating. The bulb with attached stem answers for this purpose, if the head be thrown back, but the stem presses against the nasal orifice, and if this, as is often the case, be inflamed and tender, it causes stout resistance on the part of the child, and in the struggle there is risk that the wash be thrown into the eyes, unless they are covered. If the slender and straight point of the medicine-dropper be substituted for the large and blunt stem, the application can be made with less pressure and less resistance. For infants under the age of eighteen months the hand-atomizer, as found in the shops, if the point be straight and the bulb be of large size, answers the purpose, but with this objection, that two or three compressions of the bulb and as many removals to fill it will be required for each nostril. The instrument holds nearly one drachm. I have used various syringes with tapering and bulbous nozzles, and Delano's hand-atomizer as employed by Dr. Billington. The objection to the latter is that the sharp point is very apt to prick the nostril and cause bleeding if the child resist and rotate the head. In former times I prevented this accident by drawing india-rubber tubing over the point. But I believe that the best of all hand instruments in the treatment of nasal as well as pharyngeal and laryngeal diphtheria is one constructed upon the principle of Millard's atomizer, not the one with long slender point, which bears this name, but with a bulbous end. This can be used when pressed lightly on the nasal orifice, throws a heavy spray which flows through the opposite nostril, even when the head is erect, and washes the fauces with only two or three compressions. In the treatment of laryngeal diphtheria by the ordinary atomizer, I have reason to think that much of the liquid is caught upon the tongue, but this does not occur in the use of Millard's atomizer, since the bulb acts as a tongue-depressor. The steam atomizer also has an important use in the treatment of the various forms of diphtheritic inflammation.

Yours truly, J. Lewis Smith, M.D.

SHOULD PREACHERS PAY?

To the Editor of The Medical Record.

Sir: Every now and then some doctor, with a queer notion of the dignity of his profession, insists, through the columns of The Record, that preachers ought to be charged fees for medical services rendered them. If the gentleman will allow me, I should like a word with him.

It seems to be your idea then, doctor, that, not getting a fee, you receive nothing at all for such work; that it is so much charity done, and that, too, where the recipient is no object of charity. We plead guilty, in the preacher's name, to the last specification. He is no object of charity, and though I don't profess to be able to speak for all who wear the badge of the profession, I feel that I may confidently answer for the very great majority of ministers of the Gospel, when I say that if there was no question involved but a mere one of dollars and cents, they would scorn your services upon such terms. They know, however, this custom is justified by the precedent of ages upon ages gone by. They know, too, that it is one which will hold for ages yet to come, and that it originated and has been fostered in the hearts of good men in medicine, who not only did it cheerfully, but who have felt it a privilege to do it—not, possibly, recognizing any peculiar claim upon them from ministers as men, but upon the much higher consideration of respect for the cause in which these men are engaged, and a desire to aid them in it. They honor the man "for the work's sake."

But is it really true that you get nothing back? If you appreciate the benefits Christianity bestows upon a country sufficiently to have it take you to church even once a week, and you would have this matter reduced to a commercial basis, even though you be a liberal subscriber to the fund for carrying on the church work, it is not at all likely your subscription amounts to as much as you would charge a man for an hour of your office-time once a week the year round. Yet your minister serves you, not only one hour per week, but several, and serves not only yourself, but all the members of your family share equally with you in the benefit derived. Balance this account, and tell The Record, honestly, are you loser or gainer? This, however, of course has no regard to the action of such physicians as doubt that any good at all accrues from preachers and their belongings. If you be of this opinion, then by all means collect your fees. The minister certainly has no claim upon you, at least none by virtue of his office, and only upon that score does he *allow* you to do this work gratis. Only please stop with the exercise of your own prerogative, and let the rest of us have the gratification of doing the minister's practice as often as the opportunity presents itself—thankful for the opportunity, first, of rendering a small service to the God who blesses us all the same as if we were better men than we are; and, second, to attest the real dignity of a profession whose aims and ends are a thousand miles beyond being estimated at a price.

Very respectfully, John C. Bogle, M.D.

Danville, Ky., March, 1887.

MORE ABOUT THE DOCTOR'S HORSE.

To the Editor of The Medical Record.

Sir: What, in part, a doctor's horse should be, as seen by one on the border line. Be it gelding or mare, it should not be large or small, weight close to one thousand pounds for road or city; it should have small, pointed, quick-moving ears; large, bright, prominent eyes, no deep cavities about them. Face should be broad—broad between the eyes. Nose straight, nostrils large. Head as a whole small, throat thin, no enlargements about the cartilages, neck arched, mane moderate in quantity and length. Breast only moderately broad or full. A great breadth indicates weighty strength and slowness of motion. The other extreme implies want of lung-capacity. Chest and body should be moderately full; abdomen should not taper rapidly or appear tucked up—it indicates feeble digestion. When driving the dejections should be studied; well moulded and moderately firm balls are desirable. The dock should be strong and resisting when raised by the hand. Fore-limbs straight, upper arm full; lower, good-sized, not small or thin; feet large, round, spreading, concave underneath. Hind-legs straight in line of long bones, not fine; feet good-sized, not so large as fore-feet. Coat fine, not too long. Now, Mr. Young Doctor, after driving the horse, if his style and action suit you, go to the stable, see him led into and out of the stall; wait until he is fed. If oats are given him, or any other grain, and he plunges into them with a will, chews actively, works as though he enjoyed his meal and is in a hurry to get them eaten up, buy before you leave the stable if the price suits you. Of course, you should know whether or not there is existing disease of any kind. In earlier life I bought on a warrant. The brown horse generally is sound, kind, and free from all manner of tricks.

Sig.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 17 to April 23, 1887.

Smith, J. R., Lieutenant-Colonel and Surgeon. Detailed as member of board to meet in Washington, D. C., April 28th, to prepare rules and regulations for the government of the Hospital Corps of the Army. Par. 8, S. O. 92, A. G. O., April 21, 1887.

Taylor, Morse K., Major and Surgeon. Relieved from duty at Fort Sill, Ind. Ter., May 10, 1887; to proceed home, San Antonio, Tex., preparatory to retirement. Par. 20, S. O. 92, A. G. O., April 21, 1887.

Heizmann, Charles L., Major and Surgeon. Detailed as member of board to meet in Washington, D. C., April 28th, to prepare rules and regulations for the government of the Hospital Corps of the Army. Par. 8, S. O. 92, A. G. O., April 21, 1887.

Ainsworth, Frederick C., Captain and Assistant Surgeon. Detailed as member of board to meet in Washington, D. C., April 28th, to prepare rules and regulations for the government of the Hospital Corps of the Army. Par. 8, S. O. 92, A. G. O., April 21, 1887.

Moseley, Edward B., Captain and Assistant Surgeon. Ordered for duty at Whipple Barracks, Ariz. Ter. S. O. 89, A. G. O., April 18, 1887.

Cabell, Julian M., First Lieutenant and Assistant Surgeon (recently appointed). To proceed to Fort Omaha, Neb., and report in person to the commanding officer of that post for temporary duty. Par. 19, S. O. 92, A. G. O., April 21, 1887.

Official List of Changes in the Medical Corps of the United States Navy for the week ending April 23, 1887.

Russell, A. C. H., Passed Assistant Surgeon U. S. N. Ordered to duty at Naval Laboratory, New York, May 2, 1887.

A. C. Heffenger, Passed Assistant Surgeon, U. S. N. Ordered to Widow's Island, Me., to superintend building a naval hospital, wharf, and other improvements under instructions of the Surgeon-General of the Navy.

Woodruff, Charles E., Assistant Surgeon, U. S. N. Resignation accepted, to take effect April 8, 1887.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 23, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	4	1
Scarlet fever	53	12
Cerebro-spinal meningitis	4	4
Measles	75	9
Diphtheria	72	36
Small-pox	3	2
Yellow fever	0	0

Cauterization in Diphteria.—Dr. T. J. Hutton, M.D., of Fergus Falls, Minn., writes: "In The Record's report of my remarks at the Academy two errors appear which, if permitted to go uncorrected, would render my plan of treatment null and void. 1. The expression 'twenty to fifty grains of lunar caustic *to an ounce of water*,' should read 'twenty to fifty grains of lunar caustic *to a drachm of water*.' 2. I use solution of lunar caustic exclusively, having satisfied myself that a solution of nitrate of silver of equal strength by weight is not as efficacious for the purpose now under consideration."

The Earliest Reference to Syphilis (?) in the Bible.—Dr. J. H. Straughn, Lexington, Mo., writes: "I think I have discovered the earliest reference to syphilis which is to be found in the Bible. In Deut. xxviii. 27, we read: 'The Lord shall smite thee with the emerods;" in the French Protestant Bible we also read, 'hémorrhoïdes,' but in Luther's Bible the word used is 'Feigenwarzen.' Now 'Feigenwarze,' according to Adler, means 'a pimple, a venereal boil.'"

Biliousness and its Various Interpretations.—Dr. French of Noroton, Conn., writes that, on making inquiries of a woman about a former patient, he was told that the man's wife said he had "biles on the liver," which the informant interpreted as meaning abscess of the liver. Another neighbor, being asked about the same case, replied that the man had "piles in the liver, or something of that sort."

The Introduction of Cholera into Chili.—Dr. John Trumbull sends an interesting account of the mode in which the cholera found its way into Chili despite the greatest precautions taken to prevent its entrance. "No country," he writes, "could be better situated than Chili to withstand the attempted invasion of such a disease as cholera. No better boundaries could be desired than the extensive desert on the north, separating the country from Peru and Bolivia, the Pacific on the west, and the unbroken mountain range on the east. The Andes, furthermore, form a natural watershed, thus preventing contamination of the water-supply by the inhabitants of neighboring countries. the sole danger therefore lay in importation of the disease by infected clothing or in the person of fugitives from the eastern side of the mountains. Every

port of Chili was absolutely closed to vessels coming from the eastern coast of South America, and guards were stationed at the mountain passes. A dozen of the most frequented passes were thus closed, but, the winter being a dry one, the fall of snow was light, so that more than a hundred of the less well-known passes are said to have been open. The introduction of the disease was traced directly to a party of fugitives coming from the Argentine Republic. A cattle-dealer, with four servants, crossed the mountains and remained concealed for a time in the village of Santa Maria. One of the number was sick, and five days later, on Christmas, 1886, the first authentic case of cholera occurred in the person of a laborer in that village. As soon as the nature of the disease was recognized, a military cordon was placed around the infected district, and the branch railroad leading therefrom was closed. But an exodus from the place had already commenced, and on December 30th, one of the fugitives died immediately after his arrival at a small station of the main railway line, forty-five miles from the seaport. Four days later the man who had attended this case sickened and died, and thus a second centre of infection was established. This case was an exception to the general manner of the spread of the disease, the water having been the carrier of the infection. In Chili, artificial irrigation is relied upon in agriculture, and the river water is carried through small canals (*acequias*), traversing the valleys in every direction, and furnishing the supply needed for drinking, cooking, and bathing. The canals then act as sewers, the water-closets being built over them,are next used for purposes of irrigation, and finally empty again into the river. No cordon could be of avail under such circumstances, and it was along the banks of the acequias, carrying the waste matter from the village of Santa Maria, that the disease next disclosed itself. After that a section of country, miles away, but on the bank of the same river, and drawing its water-supply from this source, was invaded. As yet the disease has not spread from the district supplied by the Aconcagua River, but several suspicious cases have appeared elsewhere, and much anxiety is felt concerning the future." Dr. Trumbull's letter, of which we have been compelled from pressure of other matter to give but an abstract, possesses a peculiar interest, since it seems possible that the disease may be brought to this country from the west coast of South America. Cases of suspected cholera are said to have been noted at the Isthmus, and if the disease becomes prevalent there, there will be great danger of an invasion of our own country.

An Analysis of Two Hundred and Fifty Autopsies on Drunkards.—Dr. Formad, in a paper on the above subject, considered the most conspicuous lesions to be cyanotic induration of the kidneys, fatty infiltration of the liver, and a mammillated stomach. His cases had been those in which there had been a history of a long-continued series of debauches, the subject often dying in one of these debauches, and did not include moderate drinkers or those who perished after imbibition of an enormous quantity of alcohol without any previous chronic excesses. He thought that the exposure, irregularities, of diet, etc., incident to a state of drunkenness, had much—probably more than the alcohol itself—to do with the production of the lesions; but it was not at all possible to separate one from the other. He gave a long list of lesions considered by various authors to be results of chronic alcoholism, among which the cirrhotic liver with contraction held a prominent place. He had himself at one time considered cirrhosis a very frequent, if not almost necessary, concomitant of long-continued, excessive use of alcohol, and had even testified in court that a certain person was not likely to have been a hard drinker, because at the autopsy no cirrhosis of the liver was found. He had thought, too, that the connection between the two was so close that it was impossible to have a case of cirrhosis without a previous history of alcoholism, as is held by various authors. Therefore, it was surprising to him to meet in his two hundred and fifty autopsies with only six cases of cirrhosis of the liver with contraction. In two hundred and twenty cases the liver was considerably or even very much enlarged, the enlargement in most cases proving to be due to a fatty infiltration. Cyanotic induration of the kidney and chronic gastritis, with mammillation of the stomach, were found in nearly every case. This cyanotic induration is peculiar, and differs from the cyanotic induration due to heart disease.—*Philadelphia Medical Times.*

Nitro-glycerine in Suspended Animation.—An interesting case is reported in the *Sei-i-kwai*, a medical journal of Japan, of the resuscitation of a woman, apparently dead, by the hypodermatic injection of nitro-glycerine. A Mrs. Fraser, of Chicago, a few days after childbirth sank from collapse, and life was believed to be quite extinct. Dr. M. H. Sackersteen, who was in attendance, after having administered various remedies, was about to abandon the case as hopeless when it occurred to him to try nitro-glycerine. He injected ten drops of a solution into a vein. A minute elapsed before his patient gave a slight gasp; in another minute this was followed by three or four gasps, and after the third and fourth minutes the pulse was felt, and the heart was distinctly heard; a flush came over the face of the patient, the eyes opened, and the muscles, which had assumed the rigidity of death, gradually relaxed, and she became conscious. In a few days Mrs. F. made a good recovery. It has has been suggested that the hypodermatic injection of nitro-glycerine should be tried in all cases of collapse or death from an overdose of chloroform and shock from surgical operation. Martindale, in his "Extra Pharmacopœia," gives several forms for the administration of nitro-glycerine in solution, hypodermatic injection when the patient cannot swallow, or drops, tablets, etc., all being perfectly safe, stable, and palatable. His tablets or troches are quite attractive in appearance, and cannot be distinguished by taste from ordinary chocolate creams. No child would refuse them. —*Medical Press.*

Treatment of Psoas Abscess.—Dr. William A. Byrd, in his surgical report of St. Mary's Hospital, at Quincy, Ill., says: "There was one death from psoas abscess that was operated upon, in 1885, by making an incision at the lower portion of the abscess and passing a probe up through the sinus and opening upon the point of the probe above the ilium, then following the sinus along upward with the probe and opening at different points, so as to secure perfect drainage. He died worn out by suppuration. The autopsy revealed aberrant sinuses running down among the muscles of the pelvis and thigh that could not have been discovered by that method of operating. The next case of this kind that I saw was with Dr. J. C. Hearne, of Hannibal, Mo. In that case we cut into the pus cavity just above the pubis and laid the whole cavity open from there to the junction of the twelfth rib with the spinal column, a distance of nineteen inches. By that means every recess was reached, thoroughly cleaned and rendered as nearly aseptic as possible, although the inner wall of the cavity was the peritoneum; it was greatly thickened by the inflammatory process, and was strengthened by deep stitches of large catgut two or three inches apart, to allow of free drainage, and then a tightly-fitting bandage was applied. In five or six weeks he was up and around the streets.

Gelatine-Coated Pills.—Dr. C. C. Stockard, of Columbus, Miss., referring to a communication of Dr. Boyd concerning the insolubility of gelatine capsules, writes that he has frequently seen gelatine-coated quinine pills pass from the bowel undigested, even where there was no gastric inflammation. He has never known this to occur with freshly filled gelatine capsules, nor with gelatine-coated pills, except those of quinine. The latter he regards as so unreliable that he never prescribes them.

BALDNESS: WHAT CAN WE DO FOR IT?[1]

By GEORGE THOMAS JACKSON, M.D.,

ASSISTANT VISITING PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL, AND CLINICAL ASSISTANT TO THE CHAIR OF DERMATOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS.

THERE is probably no one subject in medicine of which the average practitioner is less informed than that of the hair. And yet the subject is important, and everyone should have a clear idea of the resources and limitations of our art in the care of the hair and the treatment of baldness. It is the aim of this paper to point out the varieties of baldness, to throw as much light as possible upon its causation, and to show what and how much may be done in the treatment of it.

The four main varieties of alopecia are: 1, Alopecia adnata; 2, alopecia senilis; 3, alopecia prematura or presenilis; and 4, alopecia areata. The last variety will not be considered at this time, as I have recently contributed a paper upon the subject to the *New York Medical Journal*—in February, 1886.

Alopecia adnata is that form of baldness which is congenital, as its name would indicate. It is comparatively infrequent. An infant is born either with a good crop of long, colored hair which early falls out, to be replaced with light-colored permanent hair, which soon grows darker; or it is born with colorless hair in greater or less abundance, which gradually becomes darker; or it is born with a perfectly bald head. In the majority of cases this last condition is transient, and in a few days or weeks the scalp will be covered with hair. All these states of hair-growth are dependent upon the time when the change of type between the fœtal and permanent hair takes place. As a rule the change is complete at birth, when we find the colorless hair; if it is delayed until after birth, we have the long, dark hair; if at the time of birth the fœtal hair has been shed, but there has not been time for the permanent hair to grow, we have he bald head.

Now all these are normal conditions, and even the last, or bald head, is only to be considered as transient alopecia adnata. But in some cases the hair-growth is delayed for months, and in some of these there is a condition of lichen pilaris present, the scalp being rough and covered with pointed papules. The hair will usually grow in time, though a few cases have been reported in which the hair never grew. Delayed dentition, or even a deficiency of teeth, has been observed in these cases.

The *cause* of this form of baldness is an arrest of the development of the hair. Upon what condition such an arrest depends we do not know. Microscopical examinations of sections of the scalp in cases of inveterate alopecia adnata show either an absolute absence of hair-follicles or an aborted development of them. In some families the disease is hereditary.

As to *treatment*, the most we can do is to attend to the general nutrition of the child and the hygiene of the scalp. Happily in most cases the disease remedies itself. The scalp should be kept free of sebaceous accumulations, and thoroughly washed with soap and water. Should the parents and friends become restive under this expectant plan of treatment, some stimulating hair-wash may be prescribed, such as will be given when we come to the discussion of alopecia presenilis. If lichen pilaris is present, the free use of soap frictions, with the tincture of green soap every day, followed by inunctions with oil, will remove the accumulation of epidermis which clogs the hair-follicles, and thus give the hemmed-in hair a chance to grow.

Alopecia senilis is that form of baldness which occurs in old age, or after the age of forty-five, and is often preceded or accompanied by grayness of the hair. When this form of baldness begins, it is progressive. Commencing upon the vertex it forms the tonsure, and from there spreads forward so as to involve the whole top of the head; or it may begin anteriorly and spread backward; or the whole top of the head may show a thinning of the hair. When complete the scalp is smooth, oily, shiny, and looks stretched. It is unaccompanied by any disease of the scalp, excepting, perhaps, a slight seborrhœa. The region it affects is that part of the scalp over the aponeurosis of the occipito-frontalis muscle, while the occipital and lateral parts of the scalp are spared. It is always symmetrical.

The *cause* of this form of baldness is a gradual sclerosis of the subcutaneous tissues of the scalp, the retrograde process beginning in the arterial supply to the scalp, a fibrous endarteritis narrowing the lumen of the cutaneous arteries, till finally the capillary circulation about the hair-follicles is obliterated. This causes a lessening of the subcutaneous fat and a narrowing of the meshes of the connective tissue. It is but one expression of that general lowering of nutrition incident to advancing years.

When the scalp is atrophied we can do nothing in the way of *treatment;* there is no cure for alopecia senilis. Prophylaxis may do a good deal in postponing the loss of hair. Of what prophylaxis consists will be shown in the next section.

Alopecia prematura is that form of baldness which occurs before the forty-fifth year of age. It is true that the dividing line is purely arbitrary, but it is convenient, and the age of forty-five is usually considered to be that of man's prime, the top of the hill of life. There are two varieties of premature alopecia, viz., the idiopathic and the symptomatic, each of which deserves separate consideration.

Idiopathic premature baldness begins at any time before forty or forty-five years of age, most commonly between the ages of twenty-five and thirty-five. Its peculiarity is that it arises uninfluenced by any antecedent or concomitant local or general disease. When it once begins, it is generally progressive. Its course is the same as that of the senile form, beginning on the vertex and proceeding forward; or beginning on the forehead and running backward; or affecting the whole top of the head. It is a process of gradual loss of vigor, and a gradual lessening of the diameter of the hair. The hairs which first fall out are replaced by those of less vigorous growth; these in their turn are shed to make way for yet weaker ones, and so the process is repeated until complete baldness results, no new hairs being produced to take the place of those which are shed. The scalp in the affected region is atrophied, and often bound down to the underlying tissues so tightly that it cannot be slid about as easily as in the normal condition. It differs from senile alopecia in the earlier age at which it occurs, and in usually being unaccompanied by other signs of

[1] Read before the New York County Medical Society, April 26, 1887.

diminished physical vigor, such as canities, loss of teeth, and dulness of sight and hearing.

The chief *cause* of this variety of baldness is heredity, and everyone has known of families in which the fathers and sons for many generations have become bald at an early age. This is due, according to Pincus (*Berl. klin. Wochenschrift*, 1883, xx., 645), to the fact that in certain families there is a tendency to an early induration of the connective tissue under the aponeurosis of the occipito-frontalis muscle, the meshes of which, becoming progressively lessened in size, gradually draw the scalp down upon the underlying tissues, and the hair-papillæ, becoming more and more pressed upon, are at first lessened in diameter and at last completely obliterated.

Improper or deficient care of the scalp and hair is another cause of early baldness, or, at least, hastens its advent in those predisposed thereto. It is a very common practice for men to souse the head daily in water, and as Ellinger (*Virchow's Archiv*, 1879, lxxvii., 549) has noted this habit in eighty-five per cent. of his cases of baldness, it is probable that it is an important etiological factor. Thinkers and brain-workers are very often bald. Eaton (*The Popular Science Monthly*, October, 1886) has recently upheld the thesis that the coming man will be bald and toothless. He found by actual count that baldness was far more prevalent among the intellectual and educated classes than among the uneducated. Thus in the audiences attendant upon churches and operas in Boston, from forty to fifty per cent. of the men were bald; while the percentage was only twelve to twenty-five among the crowds visiting cheap museums and prize-fights. In active intellectual effort the circulation of the head is increased, and the scalp sympathizes and becomes warmer than usual. This increased warmth of the scalp in thinking may operate in the same way in the production of baldness as does the wearing of tight, unventilated hats, which sweat the hair more or less. Stiff hats may cause baldness by compressing the arteries that supply the scalp. Thus F. A. King says (*American Journal of the Medical Sciences*, 1868, April, p. 416): "Baldness of the vertex is due to compression, by stiff hats, of the anterior temporal arteries in their course over the frontal protuberances, and of the occipital behind. The reason why baldness occurs in different places in different individuals is probably due to differences in the shape of the head. The little tuft of hair often observed on top of the forehead is nourished by the two supraorbital arteries which escape pressure by passing over the forehead in the slight concavities between the frontal eminences." The existence of this little island or tuft of hair depends more likely upon its being located over the belly of the occipito-frontalis muscle, and not over its tendon.

That women do not become bald so often as men is probably because they preserve the cushion of fat under the scalp longer than men do. Pincus says that their comparative exemption is due to the fact that in them "the spaces between the connective-tissue fibres in the deeper and middle layers of the scalp are much larger than in men, the skin of women during their life preserving more of the characteristics of the skin of children." Other reasons for their comparative freedom from baldness are given, such as: Because they do not wear their hats as much as men, neither are their hats so close-fitting nor made of so impermeable materials; because they give more attention to the care of the hair than men; because they seldom wet their heads; because they are not so abundantly covered with hair as are men, and therefore have less drain upon the hair-forming elements; because their hair is less often cut. Of all these reasons those of most weight are the preservation of the subcutaneous fat and connective tissue, and the greater attention paid to the scalp.

The *treatment* of idiopathic premature baldness is mainly one of prophylaxis and of hygiene. Though hosts of remedies have been proposed from time to time, and more or less vaunted, I am inclined to believe that due attention to the proper care of the scalp and to the general hygiene of the body is more reliable than any so-called remedies. Unfortunately, men who most often are bald are least inclined to give the requisite time and trouble to the care of the scalp, and therefore our results are not as good as they should be. Women, though less frequently bald, are willing to give attention to their scalps, and with them our results are better.

Prophylaxis consists in giving early and proper care to the scalp and hair, and this especially in families in which baldness is markedly hereditary. Prophylaxis should be begun at the birth of the child in such families and continued throughout life. The proper care of the scalp consists in keeping it clean by an occasional shampoo of soap and water, borax and water, or some such simple means, and in brushing and combing the hair, and in the avoidance of all things that can harm the scalp. The shampoo need not be repeated oftener than once in two or three weeks, and whenever the scalp has been washed it should be carefully dried, and some simple unctuous substance applied, such as vaseline or sweet-almond oil. Women should dry their hair by sitting before an open fire or in the sun, and should not dress it until entirely dry. The first shampoo the baby gets is to rid the scalp of the vernix caseosa. This should be most carefully done, without the employment of force, the sebaceous plate having been thoroughly soaked with sweet-oil before the attempt to wash it off is made. After it has been removed the infant's scalp is to be oiled daily until the hair is growing nicely; this is done to guard the tender scalp from injury from atmospheric and other causes. So soon as the hair is grown the scalp only needs an occasional wash to keep it clean, unless there is some sebaceous concretions, when that condition is to be treated.

The hair should be thoroughly brushed and combed daily, not in the careless way in which it is done by most people, but systematically for some five or ten minutes, and with vigor sufficient to make the scalp glow. For this we need a good brush with long, moderately stiff bristles, set in groups widely separated from each other. Such a brush will reach the scalp and brush out all dust. A comb with large, smooth teeth, set wide apart, should be used with the brush to open up the hair to the air; first a stroke of the comb and then of the brush. After the systematic brushing the stiff brush should be laid aside and a softer one used to assist the comb in parting the hair and to polish it. This operation of brushing is rather difficult for women, and most women merely employ the comb. But the stimulation caused by the brushing is very valuable and should be insisted on.

What *not* to do is of nearly equal importance with what to do, in the care of the scalp. We should not allow the use of pomades on the healthy scalp, as they are quite unnecessary if the hair is properly brushed, and by becoming rancid are apt to irritate. The daily sousing of the hair with water should be positively interdicted. Women should not use bandoline or the like sticky substances; should not pull and twist the hair in all sorts of unnatural positions; should not scorch it with curling-irons and hot pipe-stems, nor smother it under false hair. The hair needs light and air for its growth, and will not endure forever the pulling and twisting which fashion demands of its votaries. Men should not constantly wear close-fitting hats or caps. If their avocation requires their heads to be covered, they should wear ventilated, easy-fitting hats. Working under hot artificial light should be avoided, so that the head will not be sweated. Withal, the general condition of the physique should be maintained at as high a standard as possible by exercise and moderation in all things; and worry and anxiety of mind should be combated by the cultivation of a more cheerful habit of thought.

When the hair is falling the care of the scalp, as just indicated, should be continued, or, if not already practised,

begun. In addition, local stimulation must be employed. Some remarkable results in making hair grow by hypodermatic injections of pilocarpine have been reported in the medical journals. This may be tried. I have found the drug more useful in alopecia areata than in ordinary alopecia. We know that jaborandi increases the circulation of the skin, and it would seem rational to suppose that in some cases of baldness, dependent upon malnutrition of the papillæ, it might do good. Pincus, who has devoted many years to the careful study of baldness, advises the application to the scalp for from two to five minutes, on two to four successive days, of a wash of

Bicarbonate of soda.....	4 parts.
Distilled water	180 "

M.

rubbing in one or two tablespoonfuls of it with a soft hair-brush or sponge. Then a pause is made for as many days as the wash was used. On the first and second day of the interval between the applications some oil is to be rubbed into the scalp. This treatment is to be continued for a year, and if the disease is then progressive, stronger remedies are to be used. As we will have occasion to speak of a number of stimulating hair-washes when we discuss the treatment of symptomatic baldness, it will not be necessary to mention them in this place.

As a rule, the treatment of idiopathic alopecia presenilis is unsatisfactory, and we should not encourage our patients to expect to see the condition of their hair improved to any great extent under one year, at least, of treatment. But if due attention is given to the care of the scalp and hair, the fall of the hair can be checked in many cases, and that is well worth the trouble it costs.

Symptomatic premature alopecia.—By this term is meant baldness occurring before the age of forty-five, and arising from some accompanying local or general disease. It has four varieties, viz.: 1, Alopecia furfuracea or pityroides; 2, alopecia syphilitica; 3, defluvium capillorum; and 4, alopecia follicularis.

Alopecia furfuracea is that variety which is due to dandruff—a seborrhœa, or pityriasis capitis. The dandruff may be in large amount, so as to form cakes of fatty matter on the scalp, or it may be slight, in the form of thin, easily detachable scales, which fly off from the scalp and fall upon the coat-collar like snow. This variety of baldness is met with in all ages, but is most serious between the twentieth and thirtieth years of age, and is by far the most common of the different kinds of alopecia. It has two stages; during the first there is a good deal of dandruff, and the hair is dry and falls out slightly. This stage lasts from two to seven years. Then the second stage begins, when to the dandruff is added a rapid fall of the hair. The location of the baldness is the same as in the preceding forms, though it affects most often the whole top of the head. The course of the disease is progressive and more or less rapid, the hair becoming gradually thinner both as to quantity and diameter, till at last complete baldness results. With the increase of the baldness there is a continuance of the dandruff, until the hair has nearly all fallen out, when the dandruff lessens or disappears.

Alopecia syphilitica next claims our attention. It occurs in the early stage of syphilis most often, but may occur quite late in the disease. Syphilitic exanthems may be present on the scalp and body, or the baldness may be the only symptom of the disease. When it is the result of the syphilitic cachexia we will frequently find more or less dandruff, and there will be a general thinning of the hair, giving the head a peculiar look, which may be likened to the effect produced by taking a pair of dull shears and cutting the hair away in a very irregular manner, so that the head will look ragged. The head is not completely bald in any extended area, but here and there over the whole scalp are irregular, partially denuded patches. Other regions besides the scalp may be affected, the broken arch of the eyebrows being characteristic. Besides this, which may be considered the characteristic species of syphilitic baldness, we have disseminated bald spots of cicatricial tissue due to the presence of syphilitic deposits about the hair-follicles, which have undergone absorption and caused destruction of hair-follicle and scalp tissue. This latter variety belongs rather to the category of alopecia follicularis.

Defluvium capillorum is the variety of baldness which follows acute diseases, especially fevers, or occurs in the course of some cachexia, such as mercurialism. The most common form is that which follows fevers. Usually the hair does not fall out till after convalescence has begun, and then it will be very rapid, the hair coming out by handfuls at times, and the whole scalp is affected. As a rule it does not cause absolute baldness, though in some rare cases all the hair may fall from the body, as in a case of alopecia areata maligna.

Alopecia follicularis is that variety of baldness which is due to local lesions, such as the syphilides, and the parasitic disorders. The appearances presented will vary with the cause. When due to pustular diseases, such as impetigo, the patches are not larger than from the size of a silver dollar to that of the palm. When due to some diffuse inflammatory disease, such as erysipelas, the bald patches are quite large and irregular in shape, and the scalp is hyperæmic. When due to favus or ringworm the hairs are altered, becoming lustreless, dry, and split; in ringworm they are often broken off near the scalp. The bald spots of favus are covered with thick, mortar-like crusts, or are smooth, cicatricial, and of a peculiar red color. In ringworm they are covered with scales, and sometimes crusts, which are not so thick as those of favus.

The *causes* of alopecia prematura symptomatica are manifold. We have already mentioned seborrhœa sicca, syphilis, fevers, impetigo, erysipelas, and parasitic diseases. Besides these may be mentioned violent shocks to the nervous system, mental distress, parturition, lupus vulgaris and erythematosus, lichen ruber and scrophulosorum, lepra, and other cachexiæ. The baldness following fevers, and with syphilitic and other cachexiæ, is due, in most cases, to seborrhœa, but may be purely a nutritive trouble, the hair-bulbs being poorly nourished, the hair becoming loose and falling out. The baldness accompanying or following the pustular and ulcerative diseases is due to the destruction of the hair-follicles. The baldness following upon the abuse of mercury, excess in venery, and intemperance, is due to their damaging effect upon the constitution of the patient. Anything which impairs the full vigor of a man may secondarily contribute to the production of baldness, especially if he have a predisposition thereto. This predisposition is an important factor in all cases of alopecia furfuracea. We often meet with people who have had drandruff for years without alopecia; but in many subjects dandruff does cause baldness.

As far back as 1874 Malassez[1] and Chincholle[2] described a parasite as the cause of pityriasis capitis and of the baldness following it. But Bizzozero[3] has recently shown that spores, identical with those of Malassez and Chincholle, are found quite generally upon the normal human scalp. Lassar and Bishop[4] believe that alopecia furfuracea is contagious, and is frequently transmitted by barbers' brushes and combs. They explain the comparative immunity of women by the fact that they are less exposed to infection at the hands of the barber. Their experiments with the scales taken from the scalp of a man who was losing his hair rapidly, and which they made into a pomade with vaseline and rubbed upon the back of a guinea-pig and a rabbit, in each case produc-

ing baldness, are interesting, and seem to prove their thesis. They require and deserve repetition.

Much that has been given in the etiology of the idiopathic form of premature baldness, especially in regard to the use of water on the head, the wearing of hats, and the use of pomades, could be repeated here, since they tend to produce pityriasis, and in that way alopecia furfuracea.

The *prognosis* of symptomatic premature baldness will vary with its cause. When due to dandruff, it will be good if treatment is begun in time, before actual baldness is present. Even if the hair is quite thin and the scalp shows a large number of lanugo hairs, we may yet have hope, if there is no predisposition to baldness. Defluvium capillorum usually takes care of itself, and we can give our patients a favorable prognosis. Syphilitic alopecia, when dependent upon the cachexia of syphilis, is seldom permanent. The baldness following favus is permanent; that coming after ringworm is transient. Ulcerative processes are followed by permanent baldness. Pustular lesions will not cause baldness, as a rule, and if the hair is plucked early from the follicle the danger of its occurrence is lessened.

Rapid results cannot be expected from our treatment. We must have our patients understand that they must have patience and perseverance, and that the result of treatment will depend chiefly upon their faithful carrying out of directions.

The *treatment* of symptomatic premature alopecia is both prophylactic and curative. Of course, prophylaxis applies chiefly to alopecia furfuracea. If it were better understood that dandruff is often followed by baldness, it would be early submitted to treatment, and there would be fewer bald heads. The prophylaxis for this form of baldness is the same as for the idiopathic form, and need not be repeated here.

The curative treatment of alopecia furfuracea is first addressed to the ridding of the scalp of the seborrhœa or pityriasis. If there are thick crusts or cakes of sebaceous matter on the scalp they must first be soaked with oil and then removed by the shampoo. If dandruff is present in only slight amount the shampoo may be used at once. For this purpose we should use soap and water. For our soap we may choose the tincture of green soap. If the scalp is too tender for that we may use Sarg's liquid glycerine soap, Pears' glycerine soap, Castile soap, or any good toilet-soap. Or, if the scalp does not tolerate these, we may order a shampoo of eggs, made by beating up the yolks of three eggs in a pint of lime-water and adding half an ounce of spirits of Cologne, if we want perfume. Borax and water make another excellent wash. Do not stint the water. Rub the shampoo vigorously into the scalp in all directions, using either the fingers or a long-bristled, moderately stiff brush. When the scalp has been well rubbed, the soap or chosen shampoo is to be washed out with a copious stream of water of a temperature agreeable to the patient, or, if convenient, with alternate douches of hot and cold water. The scalp and hair are then to be thoroughly dried, and a little oil rubbed into the scalp. If an excess of oil has been used it may be readily removed by pulling the hair between the folds of a towel moistened with Cologne, alcohol, or ether. The shampoo should be repeated daily for a week or so, and then once every week or two.

While the care of the scalp and hair is, perhaps, the most essential element of success in the treatment of these cases, still they need stimulating treatment in addition. So many stimulants have been recommended that one is somewhat embarrassed by the excess of richness. We may use carbolic acid in alcohol, two per cent. strength; tincture of capsicum or of cantharides, one to three drachms to the ounce of water; chloral hydrate, or tincture of nux vomica, one drachm to the ounce; corrosive sublimate, one to three grains to the ounce; the stronger water of ammonia, pure, or diluted if too strong. These may be used either as lotions or ointments, separately or in combination. Then there is a wash of rum and quinine which every druggist keeps upon his shelves, and so many of the laity use. This list is by no means exhaustive, but quite sufficient.

An excellent ointment for use, as curative of the seborrhœa, is one which is known, in at least three different dispensaries, as "Bronson's Ointment," after my esteemed friend Professor E. B. Bronson, of the New York Polyclinic. It is made of

Hydrarg. ammon	℈ij.
Hydrarg. chlor. mitis	℈iv
Vaseline	ad ℥j.

M.

and when properly compounded forms an elegant pomade of the consistence of a Mayonnaise dressing, and effectual withal.

Pincus[1] advises, in the first stage of alopecia furfuracea, the rubbing of the scalp with a solution of bicarbonate of soda, strong enough to redden the skin, and following this with a compress and an oiled-silk cap to be worn all night. Unfortunately this stains the hair. In the second stage of baldness, when the hair-fall is pronounced, he advises the use either of

Tannin	gr. lxxx
Ungt. rosæ	℥j.

M.

rubbed in every night, or of

Ol. sabinæ	gtt. v –xxx
Alcohol	℥j.

M.

used in the same way. The latter he prefers, as it can be stopped for several weeks at a time, while the use of the former cannot be interrupted for more than six days. A hood is to be worn at night with either of these. The oil of savin often causes headache, nausea, vertigo, and sleeplessness, which interdict its use. Pincus further advises the use of a lotion or ointment containing two to four per cent. of lactic acid, and eight to ten per cent. of boracic acid, applied daily for two or three weeks, and then, after a pause of a few days, followed by an ointment of bicarbonate of soda, three to eight per cent. strength, for one week. Thus he alternates his ointments for one year.

Lassar (*Monatshft. f. prakt. Dermat.*, 1882, i., 131) has had good results by washing the scalp with tar-soap daily, following with a wash of

Sol. hg. bichlor. (1 in 300).	
Spt. cologne,	
Glycerine	āā ℥ij.

M.

Then the scalp is to be dried, and a one to five per cent. solution of naphthol applied. Finally, a one and a half per cent. carbolized oil is poured over the head. I fear that we would have difficulty in persuading our patients to carry out so troublesome a procedure.

Heitzmann, of our own city, reports ("Transactions of the American Dermatological Society," 1885, p. 32) favorable results from the use of crude oleum rusci in an ointment of vaseline and paraffine, in ten to twenty per cent. strength. This is to be alternated with sulphur and white precipitate ointments.

Piffard (*Journal of Cutaneous and Venereal Diseases*, June, 1885, p. 180) has had good results by using the following:

Picis liquidæ,	
Olei lavendulæ	āā ʒj.
Olei pini sylvestris	℥vj.

M.

In some cases sulphur is added at the commencement of treatment.

[1] Virchow's Archiv, 1868, xliii., 305; also, Berl. Klin. Wochenschrift, 1883, xx., 645.

Resorcin has been recommended by Ihle. I have not found it so efficacious as other remedies.

In the treatment of these cases I have seen the best results follow the systematic care of the hair, the avoidance of frequent wetting of the hair, and the use of an ointment of precipitated sulphur in the strength of one drachm to the ounce of vaseline, applied every night for a week or two, and then every other night, until the scalp no longer is furfuraceous, and then once a week for months. If care is used in applying the ointment there will be no excess of sulphur showing on the hair.

As illustrative cases of what may be done by this plan of treatment let me recite the following:

Case I.—J. D——, aged twenty. Hair has been falling steadily for past two years, excessively for last two months. Hair thin over whole top of head, dry, and dead-looking. A shampoo of borax was ordered, to be followed by the sulphur ointment, and directions as to the care of the scalp given. In three months the hair was growing luxuriantly, and the pityriasis was stopped.

Case II.—M. B——, aged twenty-six. Hair has been falling for three or four years, and over whole top of the head it is very thin. Was put upon the same treatment, and in nine months' time the hair had ceased falling, and was growing so nicely that the patient had discarded the wig which she had worn for many months.

Case III.—E. B——, aged twenty-two. Hair has been falling for two months; scalp scaly; hair thin and dry. After two months of the above treatment the scalp was looking healthy, and the hair was growing nicely.

Case IV.—Dr. A——, aged thirty-three. Hair has been falling for four years; is quite bald. After two months' treatment the fall of the hair was almost entirely checked. He reported to me, after ten months' treatment, that the hair had ceased falling, and was growing in to an appreciable degree.

Case V.—L. B——, aged twenty-two. Hair is falling and has a good deal of dandruff. After five months' treatment the scalp was in fine condition, and the hair was growing nicely.

The treatment of *syphilitic alopecia* is by the internal administration of mercury, the mixed treatment, or the iodide of potassium, according to the stage of the disease. Locally, if any lesions are on the scalp, we may prescribe a lotion of the bichloride of mercury, or an ointment of the ammoniate of mercury. If there are no lesions, then stimulating remedies may be used as in alopecia furfuracea.

Defluvium capillorum remedies itself in most cases, and only requires attention to the general condition and to the hygiene of the scalp. If this does not suffice, stimulating measures, such as those given above, may be used.

Alopecia follicularis needs the treatment appropriate to the disease present. If there are pustules on the scalp, the hair should be pulled from them.

In conclusion, I would place special emphasis upon the importance of the hygiene of the scalp; the nearer we can bring the scalp to a perfectly healthy condition, the more we can accomplish for the restoration of hair growth. Do not be too easily discouraged, nor allow your patients to despair until a year at least has been given to the faithful care of the scalp.

14 East Thirty-first Street.

In the Broncho-Pneumonia of children the treatment in Paris is ipecacuanha to the extent of vomiting the patient occasionally, the use of the bromide of potassium to quiet the cough, and the free use of alcohol. No opium is given. Mild forms of counter-irritation are applied to the chest. In croupous-pneumonia the treatment is expectant, and alcohol is used, though Professor Jaccoud gives tartarized antimony in the early stages when the patient is robust.—*Paris Correspondent of the Chicago Medical Journal.*

EXTERNAL URETHROTOMY. A PLEA FOR ITS EARLY PERFORMANCE IN MINOR TRAUMATISMS OF THE URETHRA.

By L. BOLTON BANGS, M.D.,

NEW YORK.

The object of this paper is simply to state certain propositions in regard to an operation with which you are all more or less familiar, and to invite your discussion of them. By "external urethrotomy" I mean the division of the tissues of the male perineum down to and into the urethra, for the prophylaxis and relief of stricture and its consequences, whether the stricture be acute or chronic, traumatic or otherwise. It may be qualified, according to the necessities of the case, by adding the words "with" or "without a guide;" but it is unnecessary to make the distinctions which some writers have made. Illustrations of this could be multiplied; but, for instance, Sir Henry Thompson in "Holmes' System of Surgery" separates it into "perineal section" and "external division." He limits the term "perineal section" to the cases which are impassable to any instrument, and the term "external division" to those in which one can be passed—an arbitrary distinction, because the tissues to be divided and the steps of the operation are essentially the same—the only difference being that in one the operator has no guide through the diseased urethra and in the other he has. Perhaps Gouley's definition is the most precise, viz., "external perineal urethrotomy," but it is unwieldy, and, moreover, the term which is employed in this paper is the one commonly used, and conveys to the surgical mind all the significance that is needed.

My first proposition is that the operation should be resorted to earlier than it is usually. The observation of cases which have come under my care in hospital service has led me to the reflection that their condition has been made infinitely worse by the want of timely operation. This is especially true in regard to traumatic cases. The "golden moment" is often immediately, or within a few hours, after the injury has been received, and before inflammatory processes have *fixed* the deviated urethra in a semi-cartilaginous mass which subsequent operation can never thoroughly divide. We all know the difficulty of radically curing so-called traumatic strictures. My belief is that the number of this obdurate kind would be lessened if the rule of performing early external urethrotomy were adopted in all cases which show even minor grades of injury to the urethra—for example, such as result from blows or kicks upon the perineum; or from falling astride wagon-wheels; or from falling upon stumps or sticks which penetrate the perineum and wound the urethra. If in these the presence of a tumefaction of the perineum, associated with dysuria, leads to the opinion that the urethra has received a contusion only, the operation should be done as a prophylactic, because contusion of the urethra has been known to be followed by formidable stricture at the locality. But when a few drops of blood escape from the meatus, with or *without* retention of the urine, and with or *without* obstacle to catheterism (or when it is evident that violence has been done to the urethra), the operation should be done without much delay. In the time allotted to me it will not be possible to elaborate the pathology of this part of the question, but some reasons for these statements should be given. The urethra is now damaged to a greater or less extent, probably torn at one or more points in its circumference, and the tissues surrounding it participate in the injury. The process of repair is soon to be instituted. This should go on smoothly and quietly, in order to be harmonious and conservative; but bear in mind that it is being periodically interrupted or interfered with by the necessity which exists for the urethra to perform its function. Urine is being constantly secreted. The bladder must expel its contents, and sometimes,

under the reflex agencies of the spinal cord, it does this with great violence. Even if extravasation of urine does not occur the process of repair is irritated into an inflammatory one, and cicatricial deposits, ultimately to contract, take place in and around the urethra. The same thing results in cases which necessitate and are susceptible of catheterism. The passage of the instrument is more or less irritating, and adds to the pathological status. And here it may be remarked that even these cases are not free from the danger of extravasation. I have known it to take place insidiously, little by little, into the periurethral tissues, in cases which were not supposed to require operative interference because the bladder could be emptied by the catheter.

Again, consider for a moment the pathology of another class of cases, in which the damage to the perineum and urethra has been greater. Here retention of urine has occurred. Failing in catheterism the practitioner in charge has made use of various remedial measures—opium, poultices; or, perhaps, aspiration has been resorted to, and after a while the patient feels better. His bladder ceases to trouble him, and he is at rest. In a few hours he experiences pain in the perineum, and red spots appear upon the skin, which, proving to be abscesses, are opened, and pus and urine escape. Subsequently a certain amount of restoration of the urethra takes place and some urine passes in the natural way; but finally we have a man presenting for treatment who has an indurated and strictured urethra, with urinary fistulæ communicating with the urethra at, and posterior to, the seat of original injury. What have been the steps in this case, which is one taken from actual experience? Manifestly urine has escaped from the urethra, possibly before the aspiration (or in spite of the latter, for the bladder often contracts spasmodically upon even a small amount of urine), and the patient has experienced the relief of having emptied his bladder. But this relief is temporary, for he has "voided his urine into his own tissues," which, sooner or later, have resented its presence, and inflammation with suppuration has resulted. Perhaps it may be said that healthy urine escaping into the cellular tissues does not account for the chain of pathological processes as I have stated them. Please observe that the tissues into which the urine has escaped are *already damaged*, and nature is about to *repair* them. The least additional irritation, such as the presence of even healthy urine, is sufficient to excite undue activity, and *inflammation*, rather than repair, is the result. Whatever may be the explanation of the formation of perineal abscesses in cases whose urine is presumably normal, the fact remains that we have them to deal with, and the treatment which I am advocating will, I am sure, obviate their development. In order, then, to place the urethra, with its associated muscular and nerve-structures, in the best possible condition to heal without inflammation, *rest* must be obtained for them; and further, all possible liability to extravasation of urine, with its formidable sequelæ, must be prevented. Now it seems to me that *early* external urethrotomy, before inflammation or extravasation has supervened, will meet these indications. A free linear incision through the perineum to the urethra, the latter opened, posterior to the point of injury if possible, and thoroughly distended with the forefinger, is an operation simple in execution (if performed early enough) but comprehensive in results. And what does it accomplish? It prevents the forcing of urine into the lacerated or lame urethra, and thence into the cellular planes. It enables the urine to drain away in drops, with scarcely any movement on the part of the muscles of the urethra or perineum, and without any effort by the patient. Functional activity being no longer required, physiological rest ensues. The nerve-relations of the patient are but slightly disturbed and *repair* of the injured tissues takes the place of inflammatory action.

It is obvious, then, that to obtain these ends the operation should be done at as early a moment as practicable after the receipt of the injury. I therefore submit, as a part (or corollary) of my first proposition, that the practitioner who is first called to such a case should be the one to do it. Of course, much depends upon his manual facility, and if he is at all doubtful, he should send at once for the one in his neighborhood whom he believes to possess the requisite knowledge and dexterity, without losing time in efforts at catheterism or in the giving of narcotics. A glamour of difficulty seems to have been thrown about the operation, and perhaps such an impression is conveyed by the text-books, but it should be borne in mind that for the most part these deal with cases which have become formidable because the pathological changes (which we are seeking to prevent) have already taken place. Permit me to assert that any medical man, with a fair amount of confidence and with a catheter and scalpel in his pocket-case, is competent to do the operation. The catheter may be gently passed (under ether) and the urethra opened upon it. If it be arrested, cease all further manipulations and open the urethra upon its point. The proximal end of the injured urethra, if not readily found, may be located by compressing the bladder over the pubes and causing a spirt of urine into the wound. The tissues, although they may be swollen and discolored by extravasated blood, are yet yielding, elastic, and separable, and the torn or displaced canal may be recognized by this manœuvre. A probe or the point of the catheter can then be inserted, a linear incision made, and the operation completed. If strictures are present in the penile urethra these may be treated at the same time, provided the patient's condition will allow. There is another class of cases to which the operation is applicable under this proposition. It is one in which are found perineal abscess and a urethra abnormal only from the presence of strictures of large calibre. Dr. Otis has called attention to this in his paper upon "Follicular Departure from the Urethra." In these cases it is not sufficient to evacuate the abscess and rely upon catheterism or dilatation. The urethra should be divided at the time that the abscess is opened, lest the cause of the latter persist and more deplorable results follow. In this connection permit me to cite a case which illustrates the fact that extravasation of urine may take place in spite of the fact that the urethra is open to the passage of a fair-sized instrument. I saw the patient in consultation with Dr. Craemer, of Brooklyn, by whose courtesy I am permitted to report it. J. L——, single, aged twenty-seven, was seen for the first time by Dr. Craemer on the evening of November 7th. He was found to be suffering from complete retention of urine, which had lasted for several hours. He was a reticent, uncomplaining person, and only an indefinite statement that he "had had stricture for some years" could be elicited. A No. 10 (English) soft catheter was easily introduced, and about half a pint of fetid, turbid urine withdrawn.

The next morning the catheter was again used, and twelve ounces of clearer urine drawn. The catheter was left *in situ*. The following morning it was found that, in spite of the constant drainage from the bladder, extravasation of urine had evidently taken place into the perineum and scrotum. Operation was advised and was refused by the patient. The effects of extravasation becoming more and more manifest, I was summoned, and saw the patient with Dr. Craemer a few hours later. He was then in poor condition, with a pulse of 120. Urine was escaping from the soft catheter still in the bladder. The scrotum was enormously swollen, livid in color, and on the left side of the median line was already a black mass of necrosed skin and cellular tissue, covering an oblong area two or three inches in diameter. The perineum was also deeply discolored, boggy, and so intensely swollen as to distort the raphé and bring it almost in contact with the left thigh. Plainly extravasation had been going on for some time. I counselled immediate operation, and, assent now being given, "external ure-

throtomy" was accordingly skilfully done by Dr. Craemer.

Now how can retention and extravasation of urine be accounted for in such a case as this? It might be said that the strictured urethra was suddenly plugged by mucus or muco-pus from the bladder, and that the urethra then gave way under the straining efforts of the patient. Such an explanation might be plausible or hold good in regard to a urethra which had been narrowed to filiform size; surely not in relation to one into which could be passed an instrument which *formerly* represented Sir Henry Thompson's gauge that the urethra was *not* strictured, viz., a No. 10 (English). In this case the catheter was not "bitten," not even held by the urethra, and at the time of the operation a No. 23 French grooved staff was easily and gently slid into the bladder. My own theory, based upon the study of other cases, is this: The *extravasation* was the cause of the *retention*. Thus, Otis' "Follicular Departure from the Urethra" had been quietly and insidiously taking place; that is to say, a minute quantity of urine had probably entered an ulcerated or inflamed follicle at or behind a stricture. Inflammation, with *swelling*, followed. This still further impeded the outflow of urine, and more of the latter aggravated the difficulty in the submucous tissues. The processes being reciprocal, sufficient swelling to compress the urethra finally occurred, and the more the patient strained the worse he made himself. Observe that this patient was not able to evacuate his bladder even after the catheter had been passed, and that the doctor was compelled to leave it in. My explanation of this is that the catheter could be made to traverse the urethra and "round the corners," so to speak, of the compressing obstacle, whereas the efforts of the patient simply drove his urine into the softened and infiltrated tissues. The foregoing theory was derived from observing two cases in my service at Charity Hospital. In each of these was a perineal abscess. *Before* the latter was evacuated only filiform bougies could be introduced, but after relieving the swollen and distended perineum a fair-sized staff passed readily. I therefore inferred that the swelling itself had increased the obstructing effect of the strictures.

The second proposition which I have to offer is, that the operation of external urethrotomy is in *itself devoid of danger to the patient*. Not absolutely, for this cannot be affirmed of any operation upon the living subject, but I believe that its dangers as well as its difficulties have been overstated. The danger is in the condition of the patient antecedent to the operation; or in the conditions which necessitate its performance. It is the disease of the kidneys usually present in cases of chronic stricture which predisposes to the dangers of exhausting hemorrhage and suppression of urine. I have caused search to be made in the records of autopsies of several of the large general hospitals of New York City, and have found that where death has followed the operation of external urethrotomy the patient was the subject of some debilitating, devitalizing disease, and usually of disease of the kidneys. For example, take the record of St. Luke's Hospital. Out of 140 cases of external urethrotomy for different causes there were 8 deaths; of these 4 died from the effects of diseased kidneys; 1 from chronic pyæmia, caused by abscesses in the scrotum (for which the operation was done); 1, aged sixty-one, from chronic cystitis and prostatitis; 1 from pulmonary phthisis; and 1, who had secondary syphilis, from peritonitis.

The treatment of stricture is better understood than formerly, and it is in the experience of hospital surgeons that fewer cases of extravasation of urine are now met with. And I believe, also, that in the next decade we will see fewer with perineal fistulæ and the aggravated forms of cystitis and suppurating kidneys which render the conditions of these patients so dangerous, for they will have received the benefits of treatment before serious pathological changes have taken place.

127 East Twenty-fourth Street.

THE USE OF STROPHANTHUS IN DILATATION OF THE HEART.[1]

By S. C. CHEW, M.D.,

Professor of the Principles and Practice of Medicine in the University of Maryland.

It is probable that many members of this Society are familiar with the admirable article of Professor Thomas R. Fraser, of Edinburgh, on the action and uses of strophanthus in cardiac affections, which was published in *The British Medical Journal*, in November, 1885. The article is deserving of the highest commendation for the careful way in which the observations reported were made, and the clear reasoning from those observations which it shows.

As some present may not have seen the paper, I may be permitted to refer briefly to its leading points before speaking of the use which, under its guidance, I have myself made of strophanthus in the case which I purpose to report here, and which was one of the first in which the drug was employed in America.

The strophanthus is an African plant, found both on the western coast of the continent of Africa, in Senegambia and Guinea, and on the eastern coast along the Zambesi River. It is endowed with very active properties, for which it is used by the native tribes as an arrow poison both in hunting and in war. The poison is said to be prepared from the seeds of the plant, which are formed into a paste for this purpose. These seeds contain a crystalline principle, soluble in water and in rectified spirit, with a strongly bitter taste, and not alkaloidal in character. This is found also in the leaves and bark of the plant, but in less amount than in the seeds. This principle Professor Fraser terms strophanthin. In its action upon the frog's heart strophanthus is synergistic with digitalis, increasing the strength of its contractions, more especially the contraction of the ventricle; and, when a sufficient amount is applied, producing a strong or even tetanic contraction of the ventricle, so that the heart ceases to act in extreme systole. It is asserted by Dr. Fraser that the strophanthus in like manner increases the contractile power of all striped muscles, rendering their contractions more complete and prolonged; but that the heart is more distinctly and powerfully affected than other muscles, because it receives a larger quantity of blood than others do. But while the strophanthus is like digitalis in this action, it is very much more powerful than that drug. Some experiments of Dr. Fraser on this point show that a solution of strophanthin of one part in 10,000,000 produces a ventricular contraction of a frog's heart greater in energy than that caused by a solution of digitalin of one part in 4,000; for the digitalin solution while producing the usual changes in the heart's action, *i.e.*, increasing its contractile force and slowing it, does not arrest it; but strophanthin solution stops it in extreme systole. The difference in the power of the two agents, as thus shown, is very striking. But another difference between them, and one that may be equally important from a therapeutic point of view, is this: that whereas digitalis by an action on the blood-vessels themselves, distinct from its influence on the heart, causes increased tension and resistance in these vessels, strophanthus, on the other hand, does not act in this way, except to a very slight degree, if at all. Here again the contrast in the action of the two drugs was well shown by experiment. A solution of one part of digitalin in 20,000 when passed through the blood-vessels produced in a few minutes such extreme contraction of them as to prevent the solution from passing any longer. A much stronger solution of strophanthin, one part in 3,000, on the other hand, caused no noticeable change in the vessels, while only a slight and temporary action was produced by a solution of one part in 2,000.

This difference would again seem to make in favor of

[1] A paper read before the Clinical Society of Baltimore.

stophanthus as a therapeutic agent. For it would seem likely that in embarrassment and retardation of the circulation the beneficial effect gotten from the increased power which digitalis gives the heart is, to a certain extent, antagonized and lessened by the resistance which it causes in the blood-vessels. But, on the other hand, by the use of strophanthus not only may we have increase in heart-power, but all of the power thus gained, unhampered by obstruction in the arterioles is directed against venous stasis.

These two circumstances therefore—first, more powerful action as a heart energizer, and second, non-action upon the blood-vessels—would make it probable that strophanthus is a more efficient therapeutic agent than digitalis in the treatment of cardiac dilatation and the symptoms resulting from it.

And so in the cases reported by Professor Fraser it proved to be.

The one case in which I have made use of the drug is, so far as I have yet been able to ascertain by inquiring among my professional friends, the only one in which it has been employed in this city, with the single exception of one case of later date than mine, in which Dr. I. E. Atkinson has used it, and in which either from the advanced state of disease or unsatisfactory quality of the drug, no appreciable result was obtained from it.[1]

The preparation of the drug which I have used is a tincture which was given to me by Dr. William T. Howard, to whom it was presented last summer, while he was in London, by Dr. Fraser, as a specimen made by himself. I should have used it in a number of other cases with hope of good results, but my supply of this tincture was small, and I preferred to test its value on one case as fully as was possible with the small amount at my command. In this case it has appeared to substantiate fully the claims made in its behalf by Professor Fraser.

Case.—Ella ——, aged about twenty years, came under my charge in the Hospital of the University of Maryland, in October, 1886, when I found her suffering with general cardiac dropsy. The feet and legs were considerably swollen, but the largest amount of fluid was in the abdominal cavity, which was very much distended, so that respiration was greatly embarrassed and the patient prevented from lying down. For this she had been treated with digitalis, without much benefit, and she had been twice tapped. On examination the area of cardiac dulness was much increased, the heart's impulse diffused and lessened in intensity, and a loud systolic murmur at the apex and in the scapular region showed extensive mitral insufficiency with consequent dilatation. The pulse ranged at from 112 to 120 per minute, and the amount of urine was from fourteen to sixteen ounces in the twenty-four hours. It contained no albumen. The condition of the patient indicated the use of digitalis or other agents synergistic with it; but it was evident that with the great pressure upon the abdominal viscera and upward against the diaphragm there could be no fair and satisfactory test of drugs directed therapeutically to the heart and kidneys. I accordingly tapped the girl on October 26th, drawing off more than a gallon of fluid, with the effect of relieving her extreme dyspnœa and allowing her to lie down. Two days afterward I put her upon the use of Dr. Fraser's tincture of strophanthus in the doses, at first of two drops, and after three days, of four drops, three times a day.

Now, it it is clear that in endeavoring to estimate the value of any agent given under such circumstances, there is an obvious fallacy to be guarded against. An effect really due to the tapping might be erroneously ascribed to the action of the drug; for such results as ability to take the recumbent position, and an increase in the amount of urine, could be brought about by the direct withdrawal of the fluid even more readily in many cases than by the use of medicinal agents. Against this fallacy I endeavored to guard carefully. In the first place, I ascertained that after the previous tappings, while the patient could lie down more comfortably than before, and the amount of urine was somewhat increased, yet this increase was but slight, and there was no noticeable change in the pulse either as regards diminution of its frequency or increase of its force. Prepared with this knowledge, on the second day after the tapping, October 28th, I began the use of Dr. Fraser's tincture of strophanthus in doses of two drops three times a day. In two days there was a conspicuous improvement in the patient's condition, and on the third day the dose was increased to four drops. The breathing was much easier; the recumbent position could be maintained longer; the pulse, which had pretty constantly ranged at from 112 to 120, and had not improved after the previous tapping, was reduced to 84 per minute, and increased at the same time in fulness and strength; the impulse of the heart was more forcible, and the urine was augmented in quantity from one pint or less, daily, to more than three pints. This improvement continued steadily for ten days, the patient being out of bed and walking about the ward, and expressing herself as feeling far better in every way; when, in order to guard more perfectly against the source of fallacy referred to, I withheld the drug. In two days the patient's breathing became more oppressed, the heart's impulse lessened in force, and the pulse rose above one hundred. She begged me to give her again the medicine from which she had experienced so much relief. Its use was followed as before by prompt mitigation of the symptoms; and with occasional omissions that were followed by a return of these symptoms, which were again relieved by a recurrence to the medicine, she took it until my supply of Dr. Fraser's tincture was exhausted, when, being left without the medicine, she had a return of the urgent distress. I then obtained a specimen of tincture of strophanthus from a New York importing house; but although some relief was gotten from this, yet, either from an inferior quality of the drug, or because of the more advanced and irremediable condition of the disease, the response to the medicine has become less and less, and finally has ceased to be afforded at all. The dropsy has increased in amount, the quantity of urine diminished, the heart's action has grown feebler, and the dyspnœa has become more urgent and distressing.

About one week after the reading of this paper the patient died. The post-mortem examinatiom confirmed the diagnosis of mitral incompetency and dilatation of the heart, both of which conditions were found in an extreme degree. The amount of morbid alteration in the mitral orifice and valve was very remarkable, the two leaves of the valve being destroyed to such a degree that only two small stubs were left, so that their function must have been completely lost. The circumference of the mitral orifice was converted into a hard and rough ridge of calcareous matter, and the ventricular wall was extremely attenuated. The death of the patient under such circumstances, so far from invalidating the efficacy of the medicine, showed its power the more clearly by revealing the great difficulty against which it had to contend, and which it for the time relieved.

Since my first use of strophanthus in this case I have employed it in others similar in character. I have also used it as a cardiac tonic in other cases of weak heart without valvular or other discoverable organic disease. In one case of double pneumonia, now convalescent, in which there was great danger from extreme feebleness and intermittence of the heart, it has been manifestly beneficial. Indeed, it has seemed to me to produce some good effect always in such conditions in the way of increasing the contractile power of the heart. Such uses of the drug are suggested by Dr. Fraser. But in no case has its efficacy been more conspicuous than it

[1] Dr. Atkinson has informed me since the reading of this paper that he has recently used the drug with strikingly good effect.

was in the one above reported, in which, nevertheless, the amount of disease was necessarily fatal.

That any response to a medicine should have been made under such circumstances, or any improvement have occurred, was remarkable ; and yet over and over again, in this advanced stage of disease, the most unmistakable benefit was wrought by the strophanthus.

Baltimore, April 15, 1887.

ANTIPYRINE IN MIGRAINE, PYREXIA, ETC.[1]

By T. S. ROBERTSON, M.D.,

new york.

In presenting this, my initial paper, I pray your kindly indulgence, as my subject, I fear, will not compare favorably with the average papers read before the Society. I only hope to throw a little light on a medicine that I might say we are only experimenting with at the present time, one that I hope will be a valuable addition to our therapeutic armamentarium—a remedy that in my hands, the past two years, has rarely failed in hemicrania and the pyrexia of nearly all febrile diseases. The drug I allude to is antipyrine.

Before giving my experience with the drug, I beg to give a slight history of it. First discovered by Dr. Knorr, of Munich, it was prepared synthetically by him from the constituents of coal-tar, etc. It is an oxygenated alkaloid brought into commerce in form of the free base. It forms a white crystalline powder which is easily soluble in cold water. It gives an intense coloration with chloride of iron, effects in high fever a reduction of temperature from three and a half to five degrees, without the unpleasant after-effects of quinine. The reduction of temperature takes place after half an hour ; the rise gradual without a chill. The duration of the effects lasts from six to eighteen hours. It is given in doses of from ten to sixty grains. When given hypodermatically it produces a greater reduction of temperature with greater rapidity and of longer duration than when taken internally, while the quantity so administered is smaller and the drug less frequently demanded. Hypodermatically administered, it produces no local symptoms of any general disturbances, the smarting quickly passing away.

Although antipyrine is best known for its quick action in pyrexia, which I will allude to later on, I have found it most valuable in migraine. We are well acquainted with the patients, generally neurotic, presenting themselves with the exclamation, "Cannot you do something for these frightful headaches?" Except by some narcotic we rarely succeed to the patient's satisfaction, and in using such soporific we often have to put the patient to bed, thereby incapacitating him from business, which to some is a very serious matter. I have found these headaches confined to no class of persons, or sex—their duration averaging from six to thirty-six hours, occurring at all seasons of the year, among anæmics as well as plethorics, although the majority of patients are those of neurotic tendencies. They are intermittent in character, most common in middle life, and the pain very acute. They begin generally over either eye, extending over the entire forehead, and are rarely occipital. The origin of these headaches is difficult to trace beyond the nervous system, the patients frequently being in every other respect organically well. This class of patients is generally easily worried, and their disposition hysterical. Although both sexes suffer, I find sixty-six per cent. among females, for which we have good anatomical reasons.

As my paper is not to treat of any particular disease, but of the action of antipyrine in migraine, pyrexia, etc., I will therefore proceed to give my experience with it. I first began, over two years ago, to use it as an antipyretic with remarkable success, and I may mention here, except in cases with a malarial tendency, I have used since that time no other febrifuge. Another advantage it possesses—our patients do not complain of the ringing of the ears usually following the use of quinine. I have never so far found it to leave any ill effects. It is pleasant to taste, rarely interfering with the digestive apparatus. In pyrexia I often use as high as sixty-grain doses. In one case of purulent metritis I gave forty-grain doses as often as every six hours, and kept so doing for one week, the patient making a good recovery. In the pyrexia of phthisis I find it very valuable. The reduction of temperature takes place after one or two hours; at the same time the patient becomes more comfortable and sleeps better. I find the same relief in the pyrexia of pneumonia, typhoid fever, and nearly all febrile diseases. In the pyrexia of acute scarlatino-nephritis, of acute follicular amygdalitis and pharyngitis, in the irritating pyrexia of disease, in the pyrexia of milk fever, of peritonitis, and of gastro-intestinal disturbances, Dr. Barnett, my former associate, has, by the use of antipyrine, obtained most gratifying results. In many cases of acute articular rheumatism antipyrine in combination with sodii salicylate and bicarbonate has, when persisted in for some days, yielded me very desirable cures. The acute pain was lessened, the fever disappeared, and the duration of the attack was curtailed. I have in my case-book a record of over forty cases so treated. In my hands in cases of acute amygdalitis and pharyngitis the temperature was invariably reduced to a normal status, the patient resting much more comfortably, and the disease tending to abate in a shorter time than was customary and without the formation of an abscess.

But the most pleasant results I see from the use of this drug is in migraine. I have a record the past two years of over eighty cases in which I have used antipyrine for the relief of migraine. These cases are not selected. In fifty-four the drug acted favorably in from thirty minutes to two hours. In fifteen cases the pain was much abated, and when I resorted to chloral, bromides, or other drugs, I had to use smaller doses than the patient had otherwise been in the habit of taking. The relief was greater and the attacks generally cut short. From eight cases I had little or no effect. The reports from successful cases were all in favor of this drug, not only that it was quicker in its action, but that it did not leave the ill effects generally left by other forms of medication they had been in the habit of using. The usual narcotic treatment of migraine is generally hurtful, the patient being too ready, on the slightest symptom of pain, to fly to his favorite drug, many times establishing a habit which is worse than the original disease. This objection cannot be applied to antipyrine, as it neither narcotizes nor stimulates our patients. I have recommended many patients who are subject to attacks of hemicrania to keep twenty-grain powders constantly on hand, instructing them on the first symptom of an attack to use one powder in a little Vichy, and repeat in two hours if the pain has not abated. In an editorial of The Medical Record, February 6th, of this year, I read an article in which Dr. J. Blake White, of this city, and Dr. Unger, of Berlin, are first said to have used antipyrine in migraine. I can state that over a year ago I mentioned to Dr. E. C. Seguin, Dr. C. K. Briddon, and Dr. Robert Watts, of this city, my experience with it. When I recalled the conversation to Dr. Seguin, a few days ago, he distinctly remembered it. I will not occupy any more of your valuable time, but finish by stating that in antipyrine we have a drug that is safe and quick in its action, leaving behind no ill effects, and filling a long-desired place in our therapeutic armamentarium. A number of writers in speaking of it have mentioned its tendency, owing to the rapid reduction of heat, to produce failure of the heart's action. I must say that in my experience, and I have watched its effects very carefully, I have never yet seen the slightest ill effects from its use. In a small percentage of cases an eruption simulating that of rubeola makes it appearance on face, neck, thorax, or abdomen—occasionally on the extremities. A

[1] Read before the Neurological Society, April 5, 1887.

profuse perspiration has likewise been noted and seen in some patients. These are the patients who are especially sensitive to the effects of any drugs circulating throughout the body.

I believe that in antipyrine we have a drug, *par excellence*, with which we are able to overcome high temperatures; that it may be used in diseases where an elevated temperature has been maintained for some time—and I believe that, as the drug is only a recent innovation, a careful scrutiny of the pulse for stimulation is not contraindicated; that it is to fever what opium is to pain; that it cannot compete with quinine in intermittent fevers; that in migraine an extensive field has been thrown open for its usefulness. Its method of action here appears to be by means of a reduction in the fever-pulse rate, exerting a calming of the vaso-motor system; the capillaries dilate, and local congestion disappears. Finally, I hope that these few suggestions, based on experience, may cause others to allow no opportunity for observations of its action to escape unnoticed and unpublished.

Clinical Department.

THE TREATMENT OF BURNS.

Dr. W. P. Copeland, of Eufaula, Ala., reports the following cases to illustrate the mode of treatment employed by him in burns. He writes that he does not know whether the plan has been previously recommended, but it is one that has proved very effectual in his hands:

"Case I.—A young man received severe injuries in a boiler explosion, his face, ears, and hands being very badly burned. At the time I saw him, some weeks after receiving the burn, he was being treated by daily removals of the dressings, washing the parts with warm water and castile soap, then dusting the entire burn with subnitrate of bismuth, followed by a reapplication of the bandages and of cotton anointed with cosmoline. The patient was rapidly acquiring the morphine habit, by reason of the large doses given for the relief of pain, and the burn was doing badly. I had the dressings left off, and put the hands in pasteboard boxes without any bandages, not allowing anything to rest on the burned surfaces. The ends of the boxes were cut out to fit the wrist, and they were covered with mosquito-netting to keep off flies. The face and ears were left unbandaged also, with mosquito-netting so arranged as not to touch the burned surface. On the next day the burned surface had become dry and was covered with a thin film of scab, which gradually thickened. When pus was found to be accumulating under the scab a small opening was made at one edge, and the secretions were pressed out by means of a soft, dry piece of lint. The case progressed satisfactorily and speedily to a cure, with very little disfigurement.

"Case II.—A little girl, aged two years, was standing by an open grate when her clothes caught fire and burned a place two by three inches in dimension on the right thigh. The child was treated with the usual household remedies for a week or two, but gradually grew worse and began to have fever. Being called in at this stage, I removed all the dressings and placed a perforated oval paste-board box over the burn and secured it in place by adhesive plasters, with instructions not to remove it for three days. At the end of this time it was removed, and the burn was entirely covered over with a dry crust that protected the parts, which soon healed without further trouble.

"Without taking up time and space to relate other cases, I would summarize by saying that the method, too often adopted, of daily washing off burns or open wounds with water, and removing the secretions, only breaks up the delicate adhesions that have taken place since the last dressing, and keeps up the irritation by pulling off and washing away the very substance with which nature is trying to repair the injury."

SOME TRIALS OF BERGEON'S METHOD IN THE TREATMENT OF PHTHISIS.

Dr. M. M. Johnson, of Hartford, Conn., writes: "For the last two months I have been using Bergeon's method at the Hartford Dispensary with most satisfactory results. The treatment has not been carried on long enough to enable an accurate estimate of its true value to be formed. The patients are for the most part in the advanced stages of the disease, and are treated as they present themselves without selection of the cases. A careful record of each case is being kept, however, by Drs. Root and Segur, and in time it will be possible to form some judgment of the value of the method and to determine what cases are most likely to be benefited by this mode of treatment. Thus far there has been an evident improvement in the symptoms. The night-sweats cease, the cough becomes loose and expectoration easy, the appetite improves, the patients sleep well and increase in weight, the circulation is quickened, and the cold, clammy extremities become warm. When it is remembered that dispensary patients, as a rule, live under bad sanitary conditions and are poorly nourished, so marked an improvement in so short a time augurs well for the success of the treatment, especially as the improvement took place during the inclement weather prevalent in February and March. The apparatus is similar to that already described, except that I purify the gas by thorough washing. After the carbonic acid gas leaves the generator it passes through two wash-bottles on its way to the gas-bag receiver. When administered it is forced from the bag through a wash-bottle filled with hot water, and it then passes through another bottle, where it is impregnated with the carbon bisulphide. Thus the gas is washed three times and administered at the temperature of the body. Before inserting the tube into the rectum the gas should be passed through the tubes and bottles long enough to expel all the air. When the gas is injected cold, or mixed with air, it causes severe griping pains, but when the proper precautions are used it excites no pain or discomfort."

Dr. Henry Ecroyd, Jr., of Newport, R. I., reports the following: "Dr. S——, thirty-two years of age, naturally weak, had overtaxed his mental and physical powers, which resulted in complete prostration in December, 1886. His mother died of 'lung fever,' and a sister of acute phthisis, but the family history was otherwise good. On December 20th he had a slight pulmonary hemorrhage, was delirious during the night, and when awake had a fear of impending dissolution. Examination of the chest showed flattening under the right clavicle, with prolonged and feeble respiration, but no râles. He was removed to the Newport Hospital, and on January 1st the following symptoms were noted: Temperature, 100.7°; pulse, 84; respiration, 28. On the right side of the chest there was a dulness anteriorly to the nipple, and flatness posteriorly to the angle of the scapula. Anteriorly, crepitant and subcrepitant râles, and the same posteriorly with pronounced bronchial breathing; the face and extremities were cyanotic. His condition remained practically unchanged until January 20th, at which time the symptoms assumed a more grave type; hectic developed, the evening temperature was 103.2°; pulse, 100; respiration, 32; and the pulmonary signs gave evidence of a breaking down of the lung-tissue. It was now determined to make a trial of Bergeon's method, and on the twenty-fifth Dr. Rankin and the writer administered one litre of carbonic acid gas impregnated with sulphuretted hydrogen. The subjective symptoms were a 'tingling' sensation and a peculiar but not disagreeable taste. The following morning the temperature was normal; pulse, 80; respiration, 24. On February 2d no gas was given, and that evening the patient's temperature rose to 101.2° The next day the injections were resumed, and the temperature fell 1°. After four days the treatment was discontinued to note the effect upon

the albuminuria which had developed. At that time the patient's condition was as follows: Physical appearance greatly improved, hectic gone, night-sweats decreased, appetite decidedly improved, three meals being taken each day with the addition of five pints of liquid food in the intervals; the lower part of the area of consolidation previously noted was free from bronchophony, but fine râles were heard throughout the right upper lobe. On the ninth the injections were resumed and continued for ten days. At this time the temperature was normal, a few fine moist râles were heard anteriorly at the apex, but none posteriorly, although the respiratory sounds were still feeble. The patient was able to sit up every day, and was gaining rapidly in flesh and strength."

A CASE OF SEVERE EPISTAXIS.

Dr. L. Deakley Rood, of Northampton, Mass., reports the following: "I was called in great haste one evening to see Mr. T——, twenty-seven years of age, who, the messenger said, was having a severe hemorrhage. I went at once and found the patient raising great quantities of blood. I at once instituted the ordinary treatment for such cases, and the bleeding was soon controlled. The next morning I saw the patient again. He had been raising some blood, but not very much. The pulse was small, weak, and frequent, and the patient was so prostrated that he could hardly raise his head. I had supposed that the hemorrhage came from the lungs, as all the symptoms pointed that way, but on inquiry I learned that the patient suffered from a chronic nasal catarrh, and that he was unable to distinguish odors—in fact, had never had any sense of smell. The patient recovered his strength quite rapidly, though he still occasionally raised bloody sputa. At the end of a week I made a thorough examination of the throat and nose. The larynx was fairly healthy, but the mucous membrane of the pharynx and nose was badly congested and more or less granular. A day or two later I was called again, as the patient was having another hemorrhage. This was controlled as before, but another and more obstinate attack occurred a few days later. I determined to prevent any further hemorrhage, if possible, as the patient was becoming extremely weak from loss of blood. I therefore applied solid nitrate of silver to the pharynx and nasal cavity, completely covering the mucous membrane. Twelve applications were made, and the patient never had another hemorrhage after the first application. One remarkable feature of the case is that the patient can now smell perfectly, whereas before he was absolutely without the sense of smell. My theory is that the blood ran from the nasal mucous membrane into the pharynx, and made the patient cough, when it was expectorated."

ARE SYPHILITIC ATTACKS MADE MORE PRONOUNCED BY THE WITHDRAWAL OF ALCOHOLIC STIMULANTS FROM THE INEBRIATE?

Dr. C. F. Barber, of Brooklyn, sends the following communication: "Voluminous as are the writings upon syphilis, I fail to find mention, save in a minor way, of the deleterious effects of alcohol upon the disease. True, we are cautioned again and again to induce our syphilitics to refrain from the use of alcoholic drinks, or, if habituated to their use, to curtail them as much as possible. But no stress seems to be laid upon the outcome of their abuse. It may be my misfortune to meet unfortunate cases, or perchance those made worse by neglect, but the fact impresses me most forcibly that the abuse of alcohol, while not retarding or checking the progress of the disease as to its ultimate results, causes relapses to occur more suddenly and with greater violence than they otherwise would. It may be objected that no inebriate (for it is from this class of patients I draw my inferences) takes care of himself as he should, to say nothing of following the directions of his physician. Granting the point of this statement, I nevertheless maintain that, while many neglect themselves to a dangerous degree, yet there are those who exercise more or less care and attend to their unhealthy condition. I have during my observations, extending through several years of service among this class of people, been forcibly impressed with the fact that syphilitics, as a rule, after the withdrawal of alcoholic stimulants by gradual reduction, suffer in a sudden and severe manner from the disease in some of its many forms. Whether alcohol has any controlling effect upon the disease I am unable to state positively, but certain it is that in some patients there seems to be a period of *stasis* during their excesses. I have in mind several cases in which the disease was dormant for a long period, and suddenly reappeared after a prolonged debauch. In one case this was marked by a most severe laryngitis, causing loss of voice, difficulty in swallowing (to such an extent that nothing but fluids could be taken, and these only in small quantities), swelling of the tongue, and sordes upon the tongue and inner side of the cheeks. This patient retired in apparently good health, but upon awaking the next morning found himself in the condition I have described. Another case is that of a man who invariably, after one of his debauches, is the subject of a syphilitic ulcer on the anterior pillar of the fauces. A third has to combat a serpiginous ulcer over the crest of the tibia. A fatal case which came under my observation was that of a laborer who had contracted syphilis previous to a prolonged debauch, which terminated only after he had been sent to an institution for the cure of inebriety. After being restored to apparently his healthy condition, and while at work among his fellow-inebriates, he was complained of on account of a terribly offensive odor which emanated from him. This could not have been a result of neglect of cleanliness, for he was compelled to bathe frequently. Upon examination he gave a syphilitic history, but said that he had not been troubled for some time by any manifestation of the disease. Upon the removal of his clothing there were found syphilitic papules scattered over his body, and his scrotum was found to be a complete mass of ulcers. There were also ulcers upon the inner side of each thigh. The testicles were no doubt involved; but the condition of the scrotum forbade handling, and the internal parts of the sac could not be examined. This condition had all come on within three days, as the patient had had his bath and a change of clothing, under the eye of a reliable person, but three days previous, at which time he was apparently in a perfectly healthy condition. Many other cases, varying as to intensity, might be cited, but these are sufficient to illustrate my belief. It is well for those who have the troublesome malady of inebriety to contend with to be on their guard, and at the first indication of a syphilitic nature take the case well in hand, and, by proper treatment, alleviate the sufferings which through neglect might cause results of the gravest nature."

SPONTANEOUS DELIVERY IN A CASE OF PLACENTA PRÆVIA.

Dr. B. P. Reese, of Staunton, Va., writes: "About two weeks ago I was called to see Mrs. T. C——, over forty-five years of age, of good general health, who was supposed to be pregnant about eight months. She was having slight pains at long intervals, with some hemorrhage. I directed her to remain quietly in bed and prescribed opium and camphor. Ten days later I was again called and learned that the patient had lost a good deal of blood. The vagina was filled with clots, and after removing these I found the os dilated to about the size of a half dollar. She was having very slight pains and at long intervals. I administered half a drachm of fluid extract of ergot. Dr. Gibson, who was called by me to see the case, di-

lated the os with his finger until it would have admitted the whole hand if necessary. The hemorrhage now ceased, and I repeated the ergot. The head of the child could be felt through the bag of waters, and we decided to wait upon the efforts of nature, unless some urgent symptoms presented themselves. I gave a third dose of twenty drops of ergot, and the pains soon became more frequent and forcible. The head could be felt advancing with what we supposed to be the bag of waters in front. But to my great surprise this proved to be the placenta, which came out in advance of the child with but little hemorrhage. The child appeared to be premature and was born dead. Among the other things that this case suggested to my mind was that we may sometimes be in too great a hurry to carry out the rules laid down in the text-books to deliver at once in a case of placenta prævia."

Progress of Medical Science.

The Treatment of Retro-deviations of the Uterus.—Since October, 1882, Fraenkel, of Breslau, has treated 5,180 persons suffering from gynæcological affections; of these, 936 or 18.07 per cent., were cases of retro-deviation, that is, 645 retroflexions and 291 retroversions; the latter figure, as contrasted with the number of retroflexions, proves, so Fraenkel says, the inaccuracy of Bantock's statement that retroversion is the most frequent form of retro-deviation. Of these 936 cases of retro-deviation, 417 were patients seen in private practice, and 519 were out-door patients, treated at the polyclinic; the latter class belonged to the lower walks of life, were women who, for the most part, had undergone frequent pregnancies were obliged to work hard, and had lacked the proper care during their confinements; these causes, coupled with habitual lack of suitable nourishment and rest, being fruitful in uterine misplacements, and especially retro-deviations. In forming a judgment as to the frequency and permanence of a cure in these misplacements, Fraenkel was obliged to rely on the 417 cases in private practice, not being able to follow out the results of the treatment of the out-door patients. Of these 417 patients 123 were cases where the uterus was irreducible, where no mechanical treatment was necessary, or where the patient was subsequently lost sight of; only 294 cases were left for a fair trial of the value of mechanical support. The first step in the treatment was, of course, to rectify the retro-deviation; this Fraenkel was generally able to accomplish with the hand alone, the patient being in the knee-elbow position; in only 23 cases was he obliged to make use of the sound to straighten out the uterus. In 47 cases he was compelled to call in the aid of an anæsthetic. The only pessary which Fraenkel has used for the past four years is the Thomas pessary, which, he thinks, is sure to retain the uterus in its normal position, keeps clean, and may be worn six months or more without being changed. Another advantage of this pessary is that it allows sexual connection as well as conception; it is, moreover, sufficiently flexible, may be moulded into any shape to fit the pelvis, and renders possible a permanent cure. It is hardly necessary to say that retroflexion of the uterus entails sterility, absolute or relative. Retroflexion of the gravid uterus demands only an expectant treatment—provided that symptoms dependent on stasis, or compression of the uterus or neighboring viscera, do not exist. The gravid uterus in retroflexion often spontaneously straightens itself as that organ rises out of the pelvis; it is not true, however, according to Fraenkel, that pregnancy cures the retro-deviation, which is almost sure to return after the accouchement. To prevent this, he advises, in cases liable to this accident, the application of a large Hodge pessary the eighth or ninth day after confinement. Of the 294 cases which Fraenkel has treated with the Thomas pessary, there are, he says, 24 in which there is no doubt as to an absolute and permanent cure. These patients have been continually under his observation. The average time during which the pessary was worn was a year. The maximum was twenty seven months, the minimum nine weeks and three months.—*The Boston Medical and Surgical Journal.*

The Danger of Sublimate Used in Dressing Wounds.—At a recent meeting of the Paris Biological Society, M. Lucien Butte made a communication respecting the danger of mercuric chloride when used in dressing wounds and washing out cavities. The digestive organs are those most easily affected by corrosive sublimate. When the poison has been absorbed in sufficient quantity, diarrhœa comes on a few hours after the dressing of the wound; at first it is simply watery but afterward becomes sanguinolent, and is accompanied by tenesmus, pains in the rectum, and abdominal colic, together with nausea and vomiting. Stomatitis and salivation are rarely observed. There is albuminuria, varying frequently in degree; the urine contains lymphoid and epithelial cells with granular casts. There is also severe headache, with slight transient disturbance of the intellectual faculties and insomnia. There is occasionally slight hyperæsthesia of the skin. Toward the end, although the intelligence is intact, sensation is less acute, the sight becomes dim, the pulse is weaker, the pupils contract, the temperature falls, and erythema appears, often in a very exaggerated form. The most important lesions are found in the alimentary canal, especially in the large intestine. The inflammation is generally limited to the colon, and rarely extends beyond the valve of Bauhin. There is violent hyperæmia of the mucous membrane, and the epithelium may be easily detached; the mucous membrane, which is superficially necrosed in some parts, is in others covered with a diphtheritic coating infiltrating the underlying layers. This coating is easily removed, when slight ulcerations with well-defined edges become visible. These ulcerations only affect the epithelial layer of the mucous membrane. These intestinal changes, which have been already observed by Prévost, of Geneva, have been recently studied by Charrin from an experimental point of view. Characteristic lesions are also sometimes found in the kidneys. These organs are large, pale, and anæmic, and show the changes indicative of acute parenchymatous nephritis. Moreover, at the periphery and in sections striæ are seen of irregular size and of a yellowish-white hue. Microscopic examination shows that these points and striæ are composed of deposits of amorphous masses of oxalate of lime, which are situated in the hooked tubules, and are more abundant in the cortical matter than in the pyramids. Saikowsky succeeded in producing these lesions experimentally in rodents. Prévost showed that the calcareous deposits were caused by the decalcification of the bones, which in this form of poisoning lose as much as nine or ten per cent. of their solid constituents. The peritoneum is sometimes slightly injected. The liver is generally pale and anæmic. The other organs are unaffected, excepting the brain, which, in an experiment of Doléris, was found to be slightly congested. The course and duration of the affection are variable. In some cases the patient after a time gets quite well; while, in others, death occurs in from three to fourteen days—*The British Medical Journal.*

The Cultivation of the Bacillus Tuberculosis—The Paris correspondent of the *British Medical Journal*, February 12, 1887, writes on this subject as follows: "At a recent meeting of the Paris Biological Society M. Nocard stated that the researches which he had made in conjunction with M. Roux showed that ordinary broth, gelatinized with gelatine or with gelose, was one of the best media for the cultivation of the bacillus tuberculosis, if from six to ten per cent. of glycerine be added to the broth. It was much superior to gelatinized blood, re-

commended by Koch, and was much superior even to serum with peptone and sugar, which was recommended last year by M. Nocard. The cultivations were not only richer and more abundant, but they developed much more rapidly, eighty days being sufficient to produce a very thick layer of micro-organisms. The tubercle bacillus may be cultivated under these conditions not only in a liquid, but also in a solid medium. MM. Nocard and Roux's discovery is not only of considerable theoretical interest, but also of great practical importance. It is well known how uncertain was the cultivation of tubercle bacilli in serum, and how long a time it took to obtain a result. This made experimental researches on this micro-organism, from a pathological point of view, almost impossible; but, with this new medium of cultivation, they become easy, and investigators may undertake researches that were before impossible, especially as, in a medium solidified with gelatine or gelose, they will be able to isolate the tubercle bacillus from others that may be present in the same substance."

Waking Numbness.—Dr. A. H. Smith describes, under this title, a heretofore undescribed neurosis, and reports four cases, from a study of which it appears that the numbness is something added to the normal condition. It is a purely subjective condition. There is no paralysis of motion or sensation, the tactile sense is unimpaired, there is no change in the temperature of the affected part, the surface is not blanched or mottled, there is no tenderness on pressure. These characteristics separate this condition widely from those known under the names of night-palsy, local asphyxia, digiti mortui, Raynaud's disease, erythromelalgia, and from the various paræsthesias and acroneuroses heretofore described. Doubtless the conditions upon which the numbness depends are present during sleep, but the sensation is not sufficiently strong to arouse the sleeper, and he first becomes conscious of it when awakened by some other cause. The cause of this condition is probably central, since the effect is usually symmetrical. It would seem to be connected with the lowering of the circulation which takes place during sleep, and to disappear when the circulation returns to the waking condition, whether the return be spontaneous, or the result of rubbing, etc. As to the latter, it is doubtful whether it has any other effect than that upon the general circulation which the muscular exertion would necessarily produce. As for treatment, in the only case in which the condition existed by itself, and independently of more serious conditions, ergot, digitalis, strychnia, and aconite were tried at different times, but without result. The inconvenience produced by the affection was so slight that no treatment was carried out efficiently, so that even these negative results were of no value. In each of the other cases there was a diseased condition present, to which the numbness was subordinate, and which afforded the indications for treatment. In proportion as the treatment of the underlying condition was successful the numbness disappeared. If it be true that the cause is central, no local treatment is likely to be of service.—*The American Journal of the Medical Sciences.*

The Treatment of Malarial Diseases by Picrate of Ammonia.—Dr. Martyn Clark, in charge of an Indian medical mission, has communicated the following to the *Lancet*: "Picrate of ammonia possesses valuable therapeutical properties, though it does not seem to have received the attention which it deserves. The characters, properties, and uses of this substance were carefully investigated by Dr. Dujardin-Beaumetz, and the results were communicated by him to the Therapeutical Society of Paris in 1872. The salt had previously been successfully used in the treatment of intermittent fever by Drs. Braconnot, Calvert, Aspland, Bell, and others. Dr. Beaumetz's investigations confirmed the results at which these observers had arrived, and showed that in this substance we have a valuable and efficient substitute for quinine in the treatment of malarial diseases. It appears to have passed out of mind, and, as far as I can gather, has never been used in India. My attention was directed to it accidentally in the following way: I had a patient under my care at a hill sanatorium who had suffered for seven months from severe intermittent fever of the quotidian type. Quinine, arsenic, and other antiperiodics had been, and were, freely used, but failed to give relief. After ten days' treatment the fever still recurred daily with its accustomed severity. At this juncture the local chemist told me of a remedy for fever, which he had received some years previously, but had never tried. This I found to be picrate of ammonia. I gave it to my patient, with very gratifying results. The fever did not recur next day, nor did it do so at any time during the three subsequent months in which she remained under my observation. I have since then constantly used the picrate of ammonia in the treatment of malarial diseases. There has been ample opportunity to test it fully, for Amritsar is notorious in the Punjab for its unhealthiness, and diseases of this kind are severe and frequent. During a period of four years and a half I have treated over ten thousand cases of these diseases with this agent, with the happiest results. So uniformly successful has it been that I have in our very extensive practice here given up the use of quinine and the cinchona alkaloids for the treatment of intermittent fever, and have substituted picrate of ammonia for them. A record was kept of five thousand cases of intermittent fever treated with this agent. Of this number, in nine cases only did it fail to cure, and in these quinine succeeded at once. I usually give it in doses of from one-eighth of a grain to a grain and a half four or five times a day in pill. Half a grain is a fair average dose. Thus given the result is soon visible. In the great majority of the cases treated, half-grain doses in the interval prevented the recurrence of the next attack of the fever, while in about twenty per cent. of the patients two or three attacks followed before the fever ceased. In one case of quartan ague, despite large doses of the salt, the fever recurred for six periods, gradually diminishing in intensity, and then yielded to it. It is equally successful in all the forms of ague, but it is a curious fact that the cases in which it failed to cure were all of the tertian variety. I have also employed this agent in the treatment of twenty-five cases of malarial neuralgia of various nerves, six cases of malarial headache, and one of malarial colic. In all these instances it cured completely and speedily. In remittent fever it does not appear to be of use; six cases of a severe type were treated with it without any effect. Neither is the enlarged spleen of ague benefited by it. I have given it in numbers of such cases in conjunction with ergotine with good results, but such results are secured equally by the use of the ergotine alone. My experience leads me to the conclusion that in all varieties of intermittent fever, and in malarial neuralgias, picrate of ammonia is a valuable antiperiodic, and it is an efficient and perfect substitute for quinia. It has the following advantages over quinine: 1. It is much less expensive. This is an important consideration where, as in Indian practice, hundreds of cases of malarial diseases have to be treated annually. 2. The dose given is very much smaller. 3. It does not produce the unpleasant effects that quinine does—headache, deafness, tinnitus, etc.; nor does it disorder the digestion or cause nausea, as quinine is apt to do, in the doses in which it has to be given in India."

Urethritis without Gonococci.—Chazeaux claims (*Lyon Médical*) that there occurs among rheumatics a virulent urethritis in which gonococci are wanting; that it is characterized by a purulent urethral discharge and other symptoms of blennorrhagia; that the entire absence of gonococci is the only positive point in differential diagnosis; that the rheumatic diathesis can of itself produce this disease, contagion or a specific organism being wanting.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

PHYSICAL TRAINING AND MENTAL CULTURE.

THE Annual Report of the State Reformatory at Elmira, recently issued, contains an interesting account of an experiment made to determine the value, if any, of physical culture in stimulating the mental faculties. The results, while not startling, were yet sufficiently noticeable to mark the experiment as a success.

A class was formed of twelve men, ranging in years from nineteen to twenty-nine, who had made no progress in their school work, and seemed incapable of prolonged mental effort, but who could not be classed among the feeble-minded. None of them had learned any trade, and their ignorance was almost phenomenal, many of them not even knowing the name of the State or country in which they lived. The plan followed embraced the substitution of a special dietary for the regular prison fare, frequent bathing, followed by passive exercise, kneading of the muscles, rubbing, and a manual drill and calisthenics. The course of studies pursued was the same for all, the general level of intelligence being so nearly even that no advantage was given to any by such an arrangement. The class was formed on June 5th, and was discontinued on November 6th.

The daily routine of the men forming the class was the following: Breakfast, consisting of eight ounces of bread with butter, and a pint of coffee or cocoa, was served at six o'clock. At eight o'clock the class went to the schoolroom. At half-past nine one-half of the number went to the bath. The men bathed three times a week, taking one vapor and two tub baths one week, and one tub and two vapor baths the next week. After the bath the body was spatted until the skin was in a glow, when the muscles were kneaded and pinched, passive motions of the joints were made, and then followed brisk rubbing with a coarse crash towel, all being done by a professional trainer. After the bath the men would generally sleep until dinner. Dinner was at twelve o'clock, and consisted of about five ounces of meat or ten of fish, and from nine to sixteen ounces of vegetables. After dinner they were put through a drill, supplemented with the use of dumbbells, lasting for about two hours. Supper was at five o'clock, and consisted of eight ounces of bread with butter, and one pint of tea, cocoa, or milk.

"With physical culture and improvement," reports the medical officer, Dr. Wey, "there came a mental awakening. For the five months preceding the experiment the average marking of the twelve men in school work, according to the school register, was 45.25 out of a possible 100, and during the five months of the experiment, 74.16. Figures are misleading and statistics frequently express nothing. The measure of improvement in these twelve men can hardly be expressed in numbers, but must be judged rather by the work they accomplished than by a numerical scale. The acquisition of mere book-learning was not so much an object as to determine if physical culture in men of coarse fibre and blunted sensibilities could not be made a means to mental effort and awakening. To those of us who were thrown in daily contact with the men a mental awakening was apparent, and, upon the whole, the results obtained were as great as we had reason to expect. The men became interested in their studies and strove to appear to the best advantage in the school-room, working diligently in their cells with pencil and paper to master their tasks."

The secretary of the schools, Mr. R. B. Corey, bears similar testimony concerning the progress made. He reports: "Upon realizing that an opportunity to better themselves was being offered, all the class entered heartily into the work. As their minds brightened, from being fairly contented to remain in the lowest grade an ambition to earn perfect records guided the conduct and work of all. At the present writing one man has reached the first grade, and the remaining eleven are in the second grade. The results proved that the mental faculties of the class of men under consideration can be awakened by the breaking up of former lines of conduct and by a physical training, corresponding to that enforced in this case. The record of perfect months has caused the class to use every effort to reach the first grade, and this desire, together with the educational progress already made, will undoubtedly tend to hold the men up to the average and progress that are demanded in the classes to which they are assigned."

It is difficult to say whether this awakened ambition in the minds of the men composing the class was in consequence of the improved physical condition, or was the result of a psychical impression produced by the novelty of their position. They were picked out from their fellows for a certain work, and were doubtless proud of their distinction. This, as well as their improved physical condition, made them feel in better spirits and better humor, and consequently they were in better mood for study. As Dr. Wey remarks, it will be interesting to note, now that the class has come to an end, and physical culture and stimulation as a means to an end have been discontinued, whether the men, assigned to the various shops and distributed among the primary classes, will be able to develop the mental power that the summer's work has revealed, or whether they will sink back to the level where they were before the experiment was begun.

PHYSIOLOGY "AS SHE IS TAUGHT."

A GREAT deal more has been made of the little work "English as She is Taught" than deserves to be the case. There are stupid children everywhere, and a compilation of their stupidities does not necessarily reflect upon their teachers. We should be much interested in seeing a col-

lection of examples of "Medicine as She is Taught," compiled from the green-room experiences of our medical faculties. We fancy that the misconceptions of public-school children would dwindle into superlative insignificance in comparison, as the following illustrations taken from the Western press will show: A student is asked to report a case and responds with this result:

"*History of present illness:* Stranded himself and spit of a brite red collor. *Present condition:* 'Have you any feaver or nite swets?' 'No.' Very little expanshun of scapular in rite. *Fisical examinashun:* Exagerated breading, herd fricton sounds. Herd snores valves [this statement much puzzled the examiners, ultimately they concluded the candidate referred to 'sonorous râles']. *Prognosis:* Can't be cured, but can be sent to mexico."

While too much should not be inferred from such specimens, the selections from "English as She is Taught," showing "Physiology as She is Taught" in our public schools are not only amusing, but have a suggestive interest. We append them here:

"Physillogigy is to study about your bones stummick and vertebry.

"Occupations which are injurious to health are carbolic acid gas which is impure blood.

"We have an upper and a lower skin. The lower skin moves all the time and the upper skin moves when we do.

"The body is mostly composed of water and about one-half is avaricious tissue.

"The stomach is a small pear-shaped bone situated in the body.

"The gastric juice keeps the bones from creaking.

"The Chyle flows up the middle of the backbone and reaches the heart where it meets the oxygen and is purified.

"The salivary glands are used to salivate the body.

"In the stomach starch is changed to cane sugar and cane sugar to sugar cane.

"The olfactory nerve enters the cavity of the orbit and is developed into the special sense of hearing.

"The growth of a tooth begins in the back of the mouth and extends to the stomach.

"If we were on a railroad track and the train was coming the train would deafen our ears so that we couldn't see to get off the track."

Such examination answers as the above lead one to the suspicion that the mysteries of the human body are not made very clear to public-school children.

Physiology and anatomy are difficult studies. Correct notions of our body and its functions can only be obtained by objective teaching, and then only where the student has some maturity of general knowledge. These studies should, therefore, be placed as late as possible in school courses.

THE TREATMENT OF PHTHISIS BY GASEOUS INJECTIONS.

The reports and discussions at a recent meeting of the Practitioners' Society, published elsewhere, give the first results of the experience of New York physicians with the Bergeon method of treating consumption. The cases so treated are not many, but those reported upon were all of a serious character, and the treatment has at date of writing been continued for nearly ten weeks. Improvement occurred under the use of the injections, but no striking results were obtained, and the conclusion so far reached seems to be that while there may be "something in it," the treatment is very far from a specific for consumption.

A substitute for the method has been proposed by Dr. Szerlecki, of Lyons. He thinks that the injections act through the stimulating influence of the carbonic acid gas on the respiratory centre, and through the disinfectant properties of the sulphurous acid. He, therefore, suggests submitting patients to an atmosphere containing one per cent. of CO_2, and 0.05 per cent. of sulphurous acid.

CHRISTIAN HEALING FROM A CHRISTIAN STANDPOINT.

We have so often been obliged to criticise the clergy, and especially such as control religious journals, for aiding and abetting medical quackery, that we turn with pleasure to a recent sermon, by the Rev. E. C. Ray, of the First Presbyterian Church, at Hyde Park, Ill., a report of which lies before us. The discourse is on the subject of mind-cures, faith-cures, etc., and its tenor may best be judged by a few extracts. The preacher says:

"*Apparent cures* are often followed by a relapse, temporary improvement by permanent decline. From reported cases of cure we must deduct many of unreported relapse; it is not in human nature, when a wonderful cure has been published abroad, to follow it up with an account of the relapse coming afterward.

"*Mistaken diagnosis* accounts for many supposed cures. Physicians often, patients more often, mistake the nature of a disease. Temporary swellings are called malignant tumors or cancers (thus cancer-doctors get their reputations); hysteria simulates almost every other disease, so as to deceive even the most elect of doctors; dyspepsia produces symptoms of heart-disease or other deadly illness. There can be no question that a large proportion of faith-cures and mind-cures, and a considerable proportion of cases under ordinary medical treatment, are cases of mistaken diagnosis, the disease being less serious in its nature than was supposed.

"*Mistaken prognosis* accounts for many cases; mistake as to what would be the outcome of the disease if no curative methods were employed. It is a truth seldom recognized by patients, though well known to physicians, that *in most cases not hopelessly fatal from the start, there is from the start a strong tendency toward recovery.* Dr. Austin Flint, Sr, than whom perhaps no abler physician has lived in this land, always urged upon his students the truth that not drugs but *vis medicatrix naturæ*, the healing power of nature, is the means of recovery. The wise physician and nurse seldom attempt more than gently and humbly to assist nature in her curative processes.

"Let me add the statement of a conviction derived from some years of such close scrutiny of medical practice of various schools as a pastor has good opportunity for—a conviction agreed to, I think, by most physicians. *The benefit of medicine is often not its direct action upon the disease or upon the body, but its action upon the mind,*

and through that upon the nervous system and the whole body, stimulating faith, hope, expectation of recovery, good cheer, which are probably nature's mightiest remedial assistants."

Discussing the question whether Christians can properly accept the theories and theological inductions of the supporters of faith- and mind-cures Mr. Ray says:

"In view of the positions thus far taken I am clear that faith-cure and mind-cure make no reasonable demand upon us to accept their theories of philosophy or of theology.

"It is clear to my mind that both the faith-cure and mind-cure theories are, though in widely different degrees, perversions of the Gospel, and injurious. A Christian may hold either one and still be a true child of God; for happily theological views are of far less importance than heart-love for God and man; but unfortunately perversions of the Gospel in the long run always do serious harm to other hearts and lives. I shall not now discuss the theology of the faith-cure, which I have on another occasion shown you to be unscriptural.

"It is also abundantly in evidence that while faith-cures and mind-cures, by their influence over the patient's hope and courage, often cure disease; yet, being ignorant of the human body, of anatomy, physiology, and pathology, and depriving sufferers of intelligent and skilled medical and hygienic advice and needed medicines, they not seldom cause death in cases which might have been relieved by proper treatment. They assume in their fanatical ignorance a responsibility which is fearful, and sometimes produces results inexcusable and criminal."

It is not often that such sound doctrines emanate from our brothers of the cloth.

THE AVERAGE INCOME OF THE FAMILY DOCTOR.

The average income of the family doctor in England, according to estimates made by Dr. E. Paget Thurstan in *The Lancet*, is £625 or $3,225. Deducting the average working expenses and the interest on capital sunk, the average net income is estimated at $1,775. If there be included all the physicians having only salaries, as assistants, etc., or having no practice, the average net income is placed at about $1,000.

An average gross income of $3,225 is very much beyond that earned by American physicians, if we include the younger men who are still striving to establish a practice. This is the natural result of the fact that we have twice as many doctors proportionately as there are in England. We have to divide the fees.

TEMPERANCE AND STATE MEDICAL SOCIETIES.

"The days of wine banquets at medical conventions in Texas, we trust, are over, never to return," says the *Texas Medical Journal*. This is *à propos* of a decision not to have a wine banquet, or, if we understand correctly, any banquet at all, at the coming meeting of the Texas State Medical Society.

There are doubtless some excellent local reasons for omitting the banquet, and we are not disposed to question the wisdom of our vinicidal brethren of Texas. It is a mistake, however, to think that medical meetings can flourish on scientific papers, cases, specimens, etc., alone. The doctor likes, as well as anyone, to get rid of the shop at times and indulge to his heart's content in the pleasures of good fellowship. State medical societies are most prosperous and enjoyable in proportion as they give occasion for the agreeable social intercourse, combined with the presentation of well-prepared papers and discussions. It is unfortunate if the liberality of spirit and self-restraint of Texans are not so cultivated that banquets can be held at which those wishing to drink wine can do so, while those not desiring it can be served with the potable waters of the locality. Such arrangements prevail at the present time in most civilized sections, and Texas is eminently a civilized and progressive country.

RAGS AND DISEASE.

In connection with the discussion recently brought by the suit of certain rag-importers to recover damages from a rag-disinfecting company in this city, we would call attention to the facts procured and conclusions adopted by the American Public Health Association.

The discussions in the daily papers upon this matter have not been temperate, to say the least, and have shown a disposition to ignore the really vital question, whether imported rags are not dangerous.

The Committee of the above association collected the following cases:

1. A rag-picker from Amsterdam introduced cholera into the city of Tilburg.

2. At Dresden a rag-picker was the first victim in that Commune.

3. At Mearsen the first one attacked with cholera was a rag-picker.

4. At Wormerveer, in 1886, rags communicated typhus fever to various people.

5. In the canton of Solothern, seventeen workmen, of whom eleven died, were seized with cholera, who were engaged among rags in the paper-mills. There was no cholera within the canton, and the rags came from a cholera district.

6. A sailor died of cholera in Europe; his clothing sent to Maine (U. S.) communicated the disease.

7. Cholera was introduced at Carthage, O., Crow Run, Minn., and Yankton, Dak., by the baggage of immigrants.

8. Nine cases of cholera, four of which were fatal, occurred at Muhlhausen (Thuringia) in 1873, introduced by clothing brought from St. Louis, in the United States, *via* Hamburg and Bremen. Rags in bales have much better conditions for preserving contagion than baggage.

The Report of the State Board of Health of Massachusetts, 1873, shows that one hundred and ninety-two cases of small-pox originated in the paper-mills of that State in 1872 and February of 1883.

The authorities consulted report hundreds of cases and numerous epidemics of contagious diseases communicated by rags.

The committee conclude that, in considering this question of disinfecting imported rags, it is well to remember these points:

1. Diphtheria and scarlet fever are very much more destructive everywhere than is small-pox.

2. Diphtheria and scarlet fever are never absent from any European country.

3. Rags collected from the homes of the people of Europe are more likely to convey diphtheria and scarlet fever than small-pox.

4. The sooner public attention is attracted to the many ways in which those diseases—scarlet fever and diphtheria—which actually destroy our people by the thousands, are introduced and spread, especially throughout the Northern States, the sooner will it become practicable to prevent the introduction of those diseases.

Although diphtheria and scarlet fever are believed to be the most important factors in connection with rags, statistics collected from paper-mills show that small-pox is much the oftener seen. Thus, as the result of Dr. J. H. Raymond's inquiries among Boards of Health and paper-mills, he found the diseases presumably carried by rags, were as follows: Small-pox, 71 cases and 24 epidemics; cholera, 1 case; scarlet-fever, 3 cases and 2 epidemics; typhoid fever, 1 case.

News of the Week.

Talmudic Medicine.—Dr. Carl von Klein writes that the so-called French work on Talmudic Medicine by Dr. Rabbinowitz includes only a part of the Talmud and is an "untasteful compilation."

Disappearance of Cholera from South America.—Despatches state that cholera has disappeared from Uruguay and the Argentine Republic, and is dying out in Chili, where there have been nearly three thousand deaths from the disease.

The Relative Smartness of Doctors' Children.—Galton has pointed out some very curious facts concerning the children of professional men. He found, from a study of the heredity of the members of some of the largest scientific societies of London, that the legal profession presented the most eminent men and the fewest idiots. The medical profession came next; and lastly clergymen, who produced the smallest number of eminent men and the largest number of idiots and feeble-minded. The lawyers gave origin to six times as many more eminent men as the clergy. The clergy gave origin to six times as many more idiots and feeble-minded as the lawyers.

Martineau's Remedy for Diabetes, to which we have already referred, is prepared as follows: Carbonate of lithium, 3 grains; arseniate of sodium, $\frac{1}{10}$ grain; carbonic-acid water, 2 pints. Effect the solution under pressure. The effervescing liquid is to be drunk at meals, mixed with claret, and the foregoing dose is to last for at least three meals, being taken at the two principal meals of the day customary in Paris. No change of diet is necessary.

Not Attacking the Root of the Matter.—The Michigan Legislature is considering favorably a bill to regulate medical practice in that State. The *Medical Age* does not favor the bill as a whole, because "it fails to deal with the question which, in our opinion, is the *fons et origo* of the evils which it is calculated to correct. It accepts the diplomas of medical colleges as a guarantee of the fitness of their possessors to practise medicine. Any medical act which does this is worthless for the end which all acts have ostensibly in view."

A Maison de Sante for New York.—An attempt is being made to establish a "private hospital for invalids," having for its design the accommodation of such patients as wish to have the advantages of a first class hotel and private hospital combined and be able to select their own physician or surgeon to attend them. The prices to be regulated according to location and accommodations.

Dr. Olshausen, of Halle, succeeds the late Professor Carl Schroeder, at Berlin.

State Medical Society of Wisconsin.—The annual meeting of this Society, was held at Oshkosh, on Tuesday, May 3d, at 8 P.M.

A Sign of Summer.—Ship Island quarantine station, off the Mississippi delta, has opened for the summer season, and quarantine has been declared by the Louisiana State Board of Health against all tropical ports where yellow fever generally prevails and where cholera is liable to exist. Until June 1st vessels will be detained only a few hours.

Water-supply and Typhoid Fever.—Dr. Charles Smart has made some comparisons between the death-rate from typhoid fever in New Orleans, a city without sewerage but using pure rain-water as its water-supply, and in Philadelphia, a city with a sewer system and a contaminated water-supply. The condition of soil in New Orleans is much worse than in Philadelphia, yet in twenty years the death-rate from typhoid fever in New Orleans, per 100,000 population, has fallen from 65 in 1866 to 16 in 1885; the average for one decade was 41.3, and for the second, 24.6. In Philadelphia the death-rate from typhoid fever, per 100,000, was 60 in 1866, and fluctuated between 41 in 1879 and 98 in 1876, while the average for the first decade was 55.8, and for the second decade it was 66.1, there being an increase of nearly 11 per 1,000. These figures point to the water-supply as the principal medium of communicating this disease.—*Sanitary News.*

Albuminuria in Diabetes.—Dr. A. Pollatschek, of Carlsbad, has published (*Zeitschr. f. klin. Med.*, xii., 4) some statistical results of the systematic examination of diabetic urine for albumen, with a view to determine whether the occurrence of the latter varies in proportion with the amount of sugar. He found that out of 1,187 specimens, containing sugar in amounts varying from traces to as much as five per cent., there occurred more or less albumen in 437. The percentage (thirty-seven) was almost the same, when reckoned on the cases examined in 1885, as on those of 1886, showing a curious uniformity. By grouping the specimens of urine according to their richness in sugar, he shows that there is no constant relation between the amount of albumen and of sugar—the lowest number of albuminurics (29.1 per cent.) occurring in cases of urine with a minimal quantity of sugar, and the highest (43.8 per cent.) in urines having from two to three per cent. of sugar.—*Lancet.*

The Death of Dr. Alfred Edwards Hooker.—We regret to record the death of our young friend, Dr. Alfred Edwards Hooker. He was born in New Haven, Conn., and was a son of the late Professor Worthington Hooker, of the Yale Medical School. He received the degree of A.B. from Yale in 1880, and (having continued post-graduate studies) of Ph.B. in 1882. In the fall of the latter year he entered the College of Physicians and Surgeons, and graduated with honor in May, 1885. On the first day of June, in the same year, he became an interne in the Presbyterian Hospital of this city, and at the time of his decease was House-Surgeon of the institution, having but a month yet to serve to complete his full term. He was stricken with diphtheria—contracted from a patient in the wards—on Saturday, April 23d, and died on the following Wednesday evening. Dr. Hooker was a young man of great promise. His professional attainments, his integrity and kindliness of heart, all greatly endeared him to his associates. He was buried at New Haven, Friday, April 29th.

University Medical College, New York.—Dr. Wesley M. Carpenter has been appointed Clinical Professor of Medicine, and Dr. A. M. Phelps, late of Chateaugay, N. Y., has also been made Lecturer on Orthopedic Surgery at this institution.

Interesting to Sportsmen.—Professor Parvin states that pruritus vulvæ may be sometimes due to wild hairs.

An English Surgeon-General and an Arabic Doctor.—Dr. Grant Bey gives an interesting account in the *Medical Annals* of the way in which Surgeon-General Hunter treated a distinguished native physician of Egypt, Dr. Sabin Pasha. The latter was president of the Egyptian Board of Health at the time of the cholera. He made a report about the origin of the epidemic not pleasing to the English surgeon. The political powers were invoked, Dr. Sabin was deposed, and the Board made practically ineffective. Dr. Hunter was knighted for these and other brilliant services.

A Case of Blackmail rather than malpractice was recently brought before the courts at Troy, N. Y. Dr. R. H. Sabin was sued by a woman for $10,000 damages on the ground of improper treatment of a case of Colles' fracture. The court dismissed the case and gave the doctor judgment against the plaintiff for $99.44.

The Amount of Alcohol or Distilled Spirits used in the Preparation of Medicines in this country annually is about seven million gallons, or about ten per cent. of the whole amount produced.

Creosote Treatment of Phthisis.—Dr. Sommerbrodt, who claims so much for the creosote treatment of phthisis, uses the following: ℞. Creosoti, 1.0; tr. gentian, 2.5; spts. vini rect., 25.00; vini xeric., q. s. ad 100. M. Sig.: One ounce t. i. d. in a wineglassful of water. The creosote is increased gradually up to 2 gm.

The Famine Specialist, Cetti, has finished an eleven days' fast at Berlin, and Professor Senator recently presented him to the Berlin Medical Society, giving a brief preliminary report of the observations made. It seems that M. Cetti is twenty-six years of age, and his weight was reduced from 57,080 gm. to 50,650 gm. during the eleven days, an average daily loss of 585 gm. Starvation was not absolute, since he was allowed to drink water *ad lib.* He also smoked cigarettes, which, however, could not be shown to have had any influence on nutrition. His general condition remained very good. The quantity of chloride of sodium eliminated in the urine sank from eight or ten grammes on the first day to less than one gramme on the last days. The temperature was always within normal limits, attaining on the seventh and eighth days nearly the physiological maximum. On these days it reached 37.4° C. (99.3° F.), at other times varying between 36.4° and 36.8° C. (97.5° to 98.6° F.); but it never rose above that level. On these two days he was not very well, complaining of colic and suffering from hiccough. The pulse was normal, but very excitable, merely sitting up in bed causing an increase of the rate from 76 to 120. Professor Senator did not enter into further details, which are reserved for later publication, but described the very thorough methods to which M. Cetti was subjected. These comprised accurate measurements of the body and estimations of the excreta, examination of the blood as to its corpuscular richness and hæmoglobin capacity, and sphygmographic studies of the pulse. Observations on the vital capacity and estimation of the oxygen and carbonic acid of respiration were made daily. Dynamometric records were kept. The urine was most thoroughly investigated, chiefly by Drs. Müller and Munk, the analysis including estimations of urea, chloride of sodium, phosphoric acid, sulphuric acid, soda, potash and ammonia, indol, phenol, acetone, and diacetic acid, and also of the digestive ferments which have been recently shown to be present in urine in certain conditions and absent in others. The saliva and the fæces were also submitted to examination.

The Indiana State Medical Society will hold its annual meeting at Indianapolis, on May 10 and 11, 1887.

Physicians' Protective Association.—The physicians of Columbus, Ind., have organized a "Physicians' Protective Association," the object of which is to protect themselves from those who are able but will not pay doctors' bills.

The Causes which make Syphilis Malignant, according to M. Fourier, are infancy and old age, scrofulotuberculosis (whatever that may be), alcoholism, malaria, hereditary or acquired predisposition, poverty and high living, insufficient treatment. But the foremost of all is getting the disease in the first place.

New Disinfectants.—At a recent meeting of the New York County Medical Association, Dr. Charles A. Leale presented samples of new antiseptics and disinfectants, which he had tested, with satisfactory results, in his own practice. The first of these was glycozone, which consists of chemically pure glycerine with four volumes of ozone. It was an entirely odorless fluid, and it effectually destroyed all bad odors. It was thus a very valuable application for cases of offensive cancer. The other agent exhibited was solution of peroxide of hydrogen, which, he said, constituted a most admirable substitute for Labarraque's solution of chloride of lime, which was very offensive to many individuals. Diluted with water, ten parts to one, it could be used in all cases for which the latter was employed; and, like the glycozone, it was entirely odorless and colorless.

Reports of Societies.

THE SIXTH GERMAN CONGRESS FOR INTERNAL MEDICINE.

Held at Wiesbaden, April 13, 14, 15, *and* 16, 1887.

PROFESSOR LEYDEN, PRESIDENT, IN THE CHAIR.

[Special to THE MEDICAL RECORD.]

WEDNESDAY, APRIL 13TH—FIRST DAY—MORNING SESSION.

AFTER the session had been called to order, the President, PROFESSOR E. LEYDEN, of Berlin, delivered the

OPENING ADDRESS.

He laid down the future work of the Congress, and also reviewed what had been done in the past. Every physician knows to what a great extent the medicine of to-day has to thank the natural sciences; he knows that science alone has saved medicine from the pool of arbitrary and inhuman speculation, and founded it anew on the basis of well-grounded facts. The physician must be a searcher of Nature. He must learn to observe, prove, and sift the causes of disease in a scientific manner. The task of the physician is, however, not yet exhausted. He has, besides the scientific problems, a practical side to which he must attend.

MEDICINE MUST BE PRACTICALLY HELPFUL.

Those who are inclined to elevate the scientific above the practical must acknowledge that medicine has not a scientific speculation but a practical need to thank for its origin. Every one who has chosen the calling of a physician must undertake its duties with conscientiousness. He must bring to his assistance, in the treatment of his patients, all the knowledge and means which, in his time, medicine will command. Medicine must be independent, quite sovereign, in this endeavor. To her there is no dogma and no method; she sees with her own eyes and hears with her own ears. Consequently the problem of medicine is not only that of the natural sciences, but there is also another problem which must be solved independently, and this must be done in every branch in its own manner. Above all things, we must not allow the consciousness of the importance of our art to fail us, for

MEDICINE IS DISTINGUISHED BEFORE ALL THE NATURAL SCIENCES

because it deals with the well-being of our fellow-men. "In this branch of the natural sciences which is called medicine," says Hüter, "is prominent the tendency to preserve the life and utility of man." This task gives to our profession its especial importance. Our age is eminently a practical one, and knowledge, to be esteemed worthy of acquisiton must be useful. In the laboratory we study the particular primary causes of disease, to investigate them in their laws, their connections, their actions. Still the experiments remain one-sided, necessarily, in that only one or few of the appearances are brought out; the great number of symptoms we can only learn at the bedside.

The first subject to come up for consideration was

THE THERAPEUTICS OF PULMONARY PHTHISIS.

DR. DETTWEILER, of Falkenstein, read the first paper on this subject. He said, through the discovery of Koch we have now won a victory over the infectious diseases, and especially over this, the most dangerous of them all. The first true efforts at prophylaxis are now practised, and we are still advancing in this line. The speaker referred to the present laudable desire of physicians to help each other in attaining the great aim in medicine, and then gave a concise historical review of all the points coming under consideration. His address closed with the following conclusions:

1. A specific treatment of phthisis has not yet been found. All investigations in this direction have so far reached no conclusion.

2. The rational treatment so far has for its object to bring the nourishment and functions of all the organs of the individual up to the physiological point. Especially is it of the greatest importance to enable the organs threatened with destruction to throw off the virus. Besides the greatest possible amount of benefit which is obtainable from fresh, bracing air, a certain degree of over-nutrition, the treatment of existing symptomatic fever, and long residence in the proper climate to insure that the patient will hold what he has gained, are essential. There must also be an accompanying treatment of the mind as well as the body, since strength both of mind and body is the surest bulwark against the first symptoms of the attack of all diseases.

3. A specific climate insuring entire immunity does not exist, and the worth of a climate depends, therefore, on the especial qualifications it possesses to attain the requirements stated in No. 2. Phthisis can be cured in any climate free from extreme changes, and the individual condition of the patient alone decides the choice, since the manner and method of living are the first essentials of proper treatment.

4. The underlying mistake in the therapy of phthisis to-day is the deeply rooted belief in the inability to obtain relief in this disease. To insure success we must enter earnestly into the case, and must sacrifice everything to the comfort of the patient and the pleasantness of his surroundings. He may have to be humored in changes from southern to mountain resorts or watering-places. The diagnosis of catarrh of the apex is bad, for catarrh of the apex is already phthisis.

5. The connection of the physician with his patient must be unbroken, and not depend on the whims of the latter; this requirement, as well as others, cannot be carried out to the letter except in an establishment or a special hospital. The part of the pedagogue and psychicist plays an important rôle in the treatment. On this account the physician must have a strong power of persuasion and a dominating will; he needs the greatest patience and resignation, true sympathy with the sufferer, and must, to use Nothnagel's words, "in this respect, if a good man, be a good lung-doctor." He then referred to the great success which had followed his individual method of cure, the so called open-air cure, which had proved, in all seasons of the year, to be his most helpful aid. Of ten hundred and twenty-two cases of pure bacillar phthisis pulmonum which had been in his institution at Falkenstein in the last ten years, one hundred and thirty two were discharged as entirely cured, and one hundred and ten as relatively cured. The last consisted of such cases as, from the condition of the lungs, the condition of the general health, and the vitality of the heart and lungs, would, from all appearances, yet become entirely cured. The speaker then gave as his opinion that, by more timely treatment, and longer duration of the treatment, much more than

HALF OF ALL CASES OF PHTHISIS CAN BE CURED,

and by following out a proper mode of life will remain cured.

PROFESSOR PENZOLDT, of Erlangen, followed with a paper on the same subject. He started with the statement that

PULMONARY CONSUMPTION CAN BE HEALED.

After proving this to his own satisfaction he discussed the question, What can prevent pulmonary phthisis? He answered this from the stand-point that its origin is nothing less than an infection coupled with a predisposition. He made the following points:

1. In the battle with the numerous and invisible tubercle bacilli which are scattered broadcast over the whole earth, the chance for eradication or control is but slight;

one can but hope that the government may take in hand this most dangerous of diseases as it has others.

2. We should seek to render harmless the nests of development of the bacilli in the tubercular patients.

THE POSSIBILITY OF DIRECT INFECTION

has long been known from clinical observation, although this origin of the disease is fortunately infrequent. Though this danger is small, yet it exists, and on this account it is the duty of the physician to call attention to the danger of intimate relationship with these patients. He must also insist on the greatest cleanliness in the care of the sick, freedom from sexual connection, and unnecessary intimacy. The physician should speak out boldly against the marriage of the tubercular, and should especially insist on the observance of the rules formulated upon our knowledge of infection. It is more nearly possible to remove the danger of infection on the part of patients in hospitals, and consequently there must be a hospital for consumptives or a department for them. The state should watch, with the greatest care, cattle suffering from murrain, as there is danger of infection from them; the well cattle should be regularly examined with respect to murrain, and the diseased animals should be removed, and, where it is possible, destroyed; the most careful examination of animals slaughtered, and of the meat put upon the market, should be made by competent medical authorities.

3. One must seek to prevent the people from forgetting the danger of infection; especially must this be the case with those who are predisposed, though others are also in danger. The nursing of children by tubercular mothers or wet-nurses, as well as kissing and tending by tubercular nurse-girls, should be positively forbidden.

Of great importance is the keeping up of the strength of resistance through very rich nourishment, especially meat diet; the carnivorous animals are less liable to tuberculosis than the herbivorous. The skin and mucous membrane should be hardened, the muscles should be developed as well as the lungs, and the heart and the respiratory organs protected from dust.

THE CHOICE OF BUSINESS

of the patient is of the first importance; the employments which insure plenty of fresh air—farmer, woodman, gardener, sailor, etc.—are to be recommended. With those who have brought the disease on them, the rules of life are in general the same as for those who have inherited the tendency.

The speaker then took up the question of the particular

CURATIVE THERAPEUTICS OF PHTHISIS.

There is, he said, no specific remedy for phthisis. On this account the greatest weight is to be placed on careful attention of the body; in the foreground is the air treatment—fresh, pure air, wherever found, must be used with faithfulness; the best locality is that where little or no phthisis pulmonum is found, or where many have already been cured. Parallel with the air treatment stands the rational nourishment.

The nourishment must be as rich as possible and consist principally of albumen easily digestible, and must be taken often—six or seven times a day. The third in order to be recommended is bodily exercise. The physician should watch over this closely, to see that it is carried out; walks, cautious climbing of mountains, gymnastics in the open air are especially to be advised. As the fourth point, the hardening of the skin in the case of stronger patients should not be neglected. Lastly, the mental treatment is to be recommended. The physician must encourage the anxious, cheer the despondent, but especially hold the reckless in check. The best guarantee for the carrying out of these rules is the treatment in a hospital, in a place possessing as great immunity from the disease as possible; for poor consumptives there is nothing better than good hospitals. The speaker begged his hearers to advocate, wherever possible, the establishment of hospitals for phthisical patients in places fitted for them. In the latter part of his address he discussed the medical treatment of phthisis.

Dr. Brehmer, of the Hospital for Consumptives, in Goebersdorf, concurred with the gentlemen who had just spoken. He thought that the discovery of the tubercular bacillus had established the therapy of phthisis upon a firm basis. The speaker dwelt particularly on the fact that the question of the immunity of a place is of the greatest weight. Such places are found especially in mountains; fresh air is there, also, a great assistance. The immunity does not depend wholly on the height, but also upon the geographical position of the place; indeed, the height must be the greater the nearer the equator it lies. According to Gauster, immunity is found in the Austrian Alps only in those places which lie at an altitude of more than two thousand four hundred feet.

Dr. Mess, of Scheveningen, Holland, said he had been treating tuberculosis for twenty-five years, in the light of the favorable experience he had had with patients in the tropical colonies of Holland. He would recommend the Germans to erect their hospitals for phthisical patients in their tropical colonies; he had cured thirty-six cases without medicine, but simply by work.

Dr. Haupt, of Soden, failed to find in the two essays just read the advice to use the mineral water of Soden, the action of which is well known to further the cure.

Dr. Theime, of Mentone, called to mind the fact that Dr. Fiedler, of Dresden, had treated his patients, suffering with lung diseases, in large airy barracks in quite a primitive manner, only giving them a cover of canvas at night. Dr. Fiedler obtained such good success that the speaker had been led to give his patients in Mentone abundance of time in the open air. He referred to the success obtained by Drs. Raymond and Apthard with tannin, and then spoke of the method of inhalation of gas used by Dr. Duremberg, of the Academy of Medicine of Paris. He had found this void of danger and followed by success. He asked the German clinicians to give this method of gas-inhalation a fair trial.

Afternoon Session.

Professor Ruhle, of Bonn, read a paper entitled

THE HEREDITY OF TUBERCULOSIS.

This was a very good continuation of the subject of the morning session. The speaker observed that from the commencement the Congress had been busy with the question of tubercular bacilli. The Congress has in a manner grown with this question, and it seems its duty not to allow it to become cold. The great discovery of Koch was made just before the opening of this Congress in 1882, and published at its first meeting. It is not to be questioned that the true tubercular poison can originate in the body. As long as tuberculosis has been discussed, heredity has been considered as influencing its propagation; there are two aids to acute infection—the poison itself, and a suitable ground to receive it. The speaker then asked how the poison gained entrance into the human race through heredity? This was investigated by Baumgartner in 1883. He was of the opinion that the poison penetrated the ovum by way of the semen; that it remained latent in the child ten years or more, and then made its first appearance. The speaker was of the opinion that this theory stood on a very weak basis. The most frequent manner of contracting tuberculosis is from a diseased person through the sputa, and also through the glands, exfoliations of the skin, or any way in which the poison may appear on the surface and be transported by means of pocket-handkerchiefs, washing, etc. The fact that the attendants in hospitals who have the care of consumptives are seldom attacked with

the disease convinced the speaker that it is not the air through which the germs are carried, but it is communicated in another mode; in fact, the way in which the members of the family kiss and fondle the patient and handle his linen. From one member of the family the tubercle goes to another. Instances can frequently be found, on inquiry, where the parents transmit the disease to their children; in such cases the family physician should put in his word of warning. It is possible that we will find that the so-called cases of heredity do not need to receive their predisposition through the semen or the mother's blood.

The speaker wished, further, to say that we should hold ourselves aloof from the idea that certain things will bring about certain forms of the disease; for instance, that pulmonary phthisis comes through inhalations, tuberculosis of the alimentary canal through the nourishment, etc. That is only a notion; and when we consider that

SCROFULOSIS IS ALSO TUBERCULOSIS,

and that undoubtedly the poison of the tubercles can remain latent an indefinite period, then we can understand that it is not so simple to lay the origin of tuberculosis to an inhalation of air or to any special primary cause. When a child had acquired a glandular tuberculosis and this heals, then after fifteen years he becomes tuberculous, according to the opinion of to-day we must believe he has had it latent in his system all this time. The speaker closed his paper with the assertion that we must abandon the theory of heredity as at present understood, and in its stead place the theory of infection, the family tuberculosis, and we should also closely study the question of scrofulosis and latency.

Professor O. Fräntzel, of Berlin, did not agree with the speaker in the statement that the attendants on the tuberculous in hospitals were not infected. He had often made the observation that these attendants died of the disease, and reported three such cases from his practice in the Charité at Berlin.

Professor Lechtheim, of Berne, made an interesting report on the

COINCIDENCE BETWEEN PERNICIOUS ANÆMIA AND TAPE-WORM.

From the case of this kind which the speaker had observed he has come to the conclusion that tape-worm (Bothriocephalus latus) plays no great part in the causation of disease, yet has its rôle. This, however, is different in the regions about the Baltic, where the people feed largely on fish. The speaker then dwelt upon the coincidence of pernicious anæmia with changes in the spinal cord. He had found the anæmia to be the cause of the disease of the cord in two cases in which there was degeneration of the posterior columns. He related the result of his investigations, and spoke of the treatment of pernicious anæmia with transfusion of blood and infusion of salt solution. The observations he had made led him to believe the transfusion of blood is of little use, and that the infusion of salt is dangerous to patients with advanced anæmia.

Professor Rindfleisch, of Wurzburg, read a very scientific article on

THE PATHOLOGICAL ANATOMY OF TABES DORSALIS,

which was listened to with great attention and received with applause.

(To be continued.)

Corsets and the Kidney.—Professor V. A. Manasseïn writes (*Vratch*, No. 8, 1887, p. 206) that he has collected a large number of cases which confirm the fact that movable kidneys are met with, other conditions being equal, in women who wear or have worn stays, far more frequently than in those who have never done so. This is true in regard both to nulliparæ and childbearing women.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, April 1, 1887.

George F. Shrady, M.D., President, in the Chair.

Dr. Henry F. Walker reported a case of

CEREBRAL EMBOLISM AND POST-PARTUM URÆMIA,

occurring in private practice, and attended by unusual symptoms and history.

"It was that of a primipara of remarkable health, who had never in her memory been in a physician's care, except once, when suffering from a catarrhal trouble, she was under a specialist's charge. She was of vigorous frame, rather inclining to stoutness. She was habituated to constant open-air exercise, to which her pregnant condition was no hindrance. The family type was healthful; but an elder sister, in a first and only pregnancy, had suffered from albuminuria, with convulsions, so that there was special watchfulness given to the condition of the kidneys during the last half of my patient's pregnancy. The urine was examined as often as once in ten days, and the last analysis was made on December 10th. At that time the report was: "Color, amber; reaction, acid; specific gravity, 1.014; chemical and microscopical examinations, negative." Previous tests had not differed materially from this. There had been at no time any albumen or casts. The low specific gravity seemed due to an unusually free renal secretion.

The night of December 16th was one of the coldest of the winter. Mrs. C—— was wakened by slight pain and a discharge of amniotic fluid. Supposing this was urine, and that the pain was intestinal, she rose, clad only in a night-dress of thin cambric, and, without waking her husband, passed into a neighboring room. The window was wide open. She closed it and went to the closet in the hall, where she remained for nearly half an hour attempting to empty bladder and rectum. Her husband was roused by her return to bed, and found it impossible to get her warm.

Pains continued, and I was summoned at 4.30 A.M.; the nurse also. On the nurse's arrival she found Mrs. C—— chilled and trembling with cold, but attributed it to "nervousness."

I was not informed of these facts till late in the progress of the case.

The child was born at noon of December 17th, after a perfectly normal labor, borne, by preference, without chloroform.

Mrs. C—— had a thoroughly natural convalescence. I saw her daily for nine days, and then desired her not to sit up until I should see her again.

On December 29th, twelve days after delivery, she began to suffer from

A SEVERE FRONTAL HEADACHE.

It differed only in severity from headaches which she occasionally had experienced, and neither nurse or family deemed it needful to acquaint me. There was a little nausea and slight vomiting.

On December 30th, as I did not call, and as the headache seemed no less, the family sent for me in the evening. My partner, Dr. Montague Swift, saw her for me. He found the pulse normal, the temperature 99½° F. The bowels had been freely moved and urine passed in usual quantity. Bromide of potassium (℈j.) and chloral hydrate (grs. v.) were administered every two hours, but without affording desired relief.

I saw Mrs. C—— on December 31st. Her head was no better. I examined the urine passed in the bed-pan and found it highly albuminous. I ordered it drawn by catheter and sent for analysis. To the patient I gave two grains of calomel and a scruple of bicarbonate of soda, and administered, with complete, immediate relief, ten drops of Magendie's solution with the needle. The morphine was thenceforward continued p. r. n.

January 1st.—The urine, drawn by catheter, was amber in color; acid; specific gravity, 1.032; contained fully twenty-five per cent. of albumen, and gave a decided saccharine reaction. The microscope showed red blood-disks, pus-cells, but no casts. The patient made no complaint save of headache when the morphine-influence was exhausted. She had a general look of fulness, but there was no œdema which would pit on pressure.

Dr. Delafield saw Mrs. C—— with me. He advised the use of caffeine in grain dose every two hours as a cardiac and renal stimulant. At this time the daily amount of urine was about two quarts. The caffeine was continued to the end. Dr. Delafield advised withholding the morphine, but the immediate return of severe headache made it needful to continue its use.

January 3d.—After a comparatively comfortable night the patient became quite restless toward morning, and had an attack of hysterical laughing and crying, with some twitching of the face and extremities. The amount of urine passed in the night had exceeded a quart. An examination of that drawn in the morning gave a specific gravity of 1.024, ten per cent. of albumen, but no trace of sugar. By microscope, pus-cells and small hyaline casts, with adherent granular matter, were found. Early in the forenoon, while making a sudden effort to rise, Mrs. C—— became

PARALYZED IN THE RIGHT ARM AND LEG.

There was some difficulty in the movement of her lips in receiving a drink, and of the muscles in swallowing. She was aphasic. Mentally she was dull.

This condition lasted through Sunday, January 4th, though there was apparent improvement in her mental action. At 1 P.M. Dr. Thomas, in Dr. Delafield's absence, saw Mrs. C—— with me, and concurred in the diagnosis of embolism. At 8.30 P.M. I saw the patient again, and found her cataleptic on the side not affected by paralysis. I gave her ten minims of Magendie's solution and she slept quietly for an hour, when, without premonition, she had a severe convulsion, lasting twenty minutes, which was finally controlled by chloroform, administered by the nurse. Dr. Draper, living near, was summoned and saw Mrs. C—— just as the convulsion passed off. He gave brandy hypodermically, which rallied the enfeebled pulse. I reached the patient at ten o'clock, and met Dr. Draper, who attributed the convulsions to the accumulating uræmic poisoning. Dr. Draper suggested the use, hypodermically, of digitalin in one-eightieth grain doses and, alternately with this, brandy hypodermically.

Mrs. C—— never rallied. She lay with head turned to the right; her pupils were contracted, perhaps due to morphine, and she breathed stertorously.

January 5th.—Save slight convulsive movements, controlled by chloroform, there was no change except perceptible loss of strength. She died at 11 P.M., from heart-failure and attendant pulmonary œdema.

My own opinion is, that in this case I dealt with an

UNUSUAL FORM OF URÆMIA:

one not due so much to the puerperal state as to an accidental exposure and consequent renal congestion.

"My reasons are—first, negatively, the entire absence of symptoms up to and for the twelve days subsequent to delivery, which days were passed without a single adverse symptom; second, and positively, the exposure to severe cold was sufficient to excite renal congestion, while the type of urine was that which would indicate such a condition of the kidneys. For the urine was, at first, loaded with albumen, and the microscope showed many red blood-disks, without casts of any kind; while later, with albumen, granular and small hyaline casts were found in large numbers.

The embolic complication of labor has not been wholly unknown to me in practice. I have seen four cases in all. In all of the cases there was albuminuria. In three there were convulsions. All occurred in primiparæ."

Dr. Dana stated that, so far as he could find, the pathology of the puerperal paralyses had been very inadequately worked up. The only comprehensive article he had seen was by Charpentier, who collected and analyzed one hundred and forty-nine cases. Embolism occurred in the minority of these cases. The current view that many, if not most, of the puerperal hemiplegias were due to embolism was not based on accurate pathological findings, but mainly on the symptomatology. The prognosis was very bad, twenty per cent. of mortality occurring in puerperal hemiplegia. Over half the cases were in primiparæ.

Dr. Beverley Robinson said that, from a clinical stand-point, he would regard the low specific gravity of the urine in Dr. Walker's case as an important indication of the presence of chronic disease of the kidneys. He added a case that occurred in St. Luke's Hospital—that of a man who at first gave no special evidence of kidney-trouble, but later on there was pronounced evidence of renal disease, and not long after that he went into a well-marked uræmic convulsion. The usual remedies failing, he bled the patient twice, and rapid recovery from the convulsions ensued.

For one, he had a decided

AVERSION TO HYPODERMIC INJECTIONS OF MORPHINE IN URÆMIC CONVULSIONS.

He did not believe that it was good teaching to advise the hypodermic use of morphine in this class of cases.

Dr. Kinnicutt believed that the theoretical objections to the use of opium in acute uræmia admitted of doubt as to their correctness, inasmuch as the exact pathology of this condition was still unsettled. In a large proportion of cases of acute uræmia markedly increased arterial tension was present, with undoubtedly an abnormal distribution of the blood throughout the body; theoretically, all therapeutic measures capable of relieving such tension might be considered as indicated. Opium certainly possessed this power in a measure, in addition to its sedative action in irritable conditions of the nervous system, and its use would therefore seem to be indicated in acute uræmia. Clinically, he had only seen good results from its use in the condition mentioned. In uræmic headache, vomiting, and convulsions, he considered opium an invaluable drug. At the same time he believed that blood-letting in certain cases of acute uræmia was of the greatest possible service. He suggested that the symptoms described by Dr. Robinson might reasonably be expected from uræmic poisoning.

Dr. Robinson did not believe that opium, as ordinarily given, either by the mouth or hypodermically in the form of morphine, produced any stimulating effect or strengthening influence on the heart, and therefore it did not stimulate the brain. The condition of the brain present just before the occurrence of the convulsion is one of anæmia.

The President remarked that there might be as much reason for believing that the convulsions were due to irritation of the nerve-centres, and that opium acted beneficially by subduing this irritation.

Dr. Robinson said it was astonishing to see how marked the relief was that was produced by a small blood-letting in these anæmic patients.

Dr. Kinnicutt did not doubt that blood-letting oftimes was very beneficial, but he would be very sorry if obliged to accept it as the only means for controlling the convulsions.

Dr. A. Brayton Ball believed that the remarkable

POWER OF OPIUM IN RESTORING THE RENAL SECRETION

ought not be overlooked. He did not know how it was to be explained, but he believed it was a fact recognized, that opium has the power to restore the renal secretion—a fact which he thought was worthy of consideration. At first he was very strongly opposed to the use of opium in these cases, because he had seen a fatal result in two instances due to its administration. But he had

changed his opinion, and was confident that he had seen a number of cases of uræmic convulsions in which opium appeared to be of very great benefit. He supposed it was a well-recognized fact that convulsions of themselves were a great source of danger, and that that fact was regarded as one of grave significance. The remedy, then, which will control these convulsions, will place the nervous system in a state of repose for the time being, and allow it to recover itself, other things being equal, possesses great advantage.

Dr. Robinson said he did not wish to affirm that bloodletting was the only means of arresting uræmic convulsions, but he thought that it was worth commenting on in connection with Dr. Walker's case.

Dr. Ball asked Dr. Walker if the practice of using morphine hypodermically was not generally adopted in this city by obstetricians.

Dr. Walker said that he thought it was. He had resorted to blood-letting in only a comparatively few cases. Of course, chloroform was used, and it was supplemented by morphine given hypodermically.

Dr. Ball remarked that morphine, hypodermically, was in general use in these cases in Bellevue Hospital.

Dr. Shrady thought that it was generally used by practitioners in the country, and he was rather surprised at the statements made by Dr. Robinson. All recollected how Dr. Alonzo Clark opposed the use of opium in chronic Bright's disease, and for a long time—and for the reasons given by Dr. Clark—Dr. Shrady was formerly opposed to the use of opium in this class of cases.

Dr. Ball was satisfied that there was a certain amount of

TRUTH IN DR. CLARK'S OPINION,

although that might not militate against the use of opium in acute uræmia. He believed it was well established that small doses of opium might produce poisonous effects in patients who had granular kidneys.

Dr. E. Darwin Hudson said that he once held to the view that opium was contraindicated in Bright's disease; that it diminished the action of the kidneys, and, therefore, the elimination of urea. But he gave up this view long ago, and had come to regard hypodermic injections of morphine as diuretic in action. Within the last two years he had had patients with chronic kidney disease to whom he had given a hypodermic injection of morphine every night with beneficial effect.

Dr. Ball mentioned a case which he saw in consultation with Dr. John G. Curtis. Dr. Curtis was counting the patient's pulse, and while doing this the heart suddenly stopped. At that instant he saw the beginning of a general convulsion. This observation confirmed what Dr. Ball had seen stated—namely, that immediately before the convulsion there is a failure of heart-action.

Dr. A. A. Smith believed that hypodermic injections of morphine were of great utility in uræmic convulsions occurring in acute renal disease. In uræmic convulsions occurring as the result of an acute attack ingrafted upon chronic renal disease of not very long duration they were of great utility. But he believed that there came a time in the course of chronic degenerative changes in the kidney, and perhaps elsewhere, when the use of hypodermic injections of morphine were

FOLLOWED BY DISASTROUS RESULTS,

and to know exactly where to draw the line when they might be safely used in chronic Bright's disease attended by convulsions was very frequently a difficult question to be answered. He felt that where chronic Bright's disease existed, and the observer knew of its presence, and knew that it had existed for some time, hypodermic injections of morphine should be used with a great deal of care.

Dr. Kinnicutt asked if any of the gentlemen present had, in their personal experience, seen bad results that could be attributed to the hypodermic use of morphine in *acute uræmia*.

Dr. Smith said that in acute uræmic convulsions he

HAD NEVER SEEN ANY BAD RESULTS.

Dr. James B. Hunter had never seen any bad results from this method of treatment.

Dr. Robinson had seen bad results in hospital practice, where there was a certain amount of reason for believing that the convulsions were due to uræmic poisoning. He had not seen that the secretion from the kidneys was increased; the convulsive attack was not, apparently, arrested; the general condition of congestion was increased, without manifest improvement in the condition of the action of the heart.

Dr. J. B. Hunter thought that the symptoms described by Dr. Robinson could not be ascribed to the morphine.

Dr. Smith cited an illustrative case occurring in a child that had had scarlet fever. The urine was very much diminished in quantity, there was œdema, and the child went into convulsions. A hypodermic injection of morphine was given, and the convulsions ceased. Within twelve hours the patient passed *ten* ounces of urine, and within twenty-four hours, *sixteen* ounces. The child got well.

GOUT OF THE HEART (?).

Dr. Walker also reported a case in which the gouty diathesis played an important part in an otherwise hazardous illness.

"I was called to see Mr. A—— in February, 1886. He was a man of fifty, of sedentary habits, and in weight turned the scale at two hundred and fifty pounds. He was subject to frequent attacks of gout, affecting chiefly the smaller joints of the feet, but occasionally involving the larger joints of both extremities. These, from frequent experience, he had "treated himself," or, rather, had done nothing for them, except to maintain quiet, preserve warmth, and wait the relief that nature brought.

I saw Mr. A—— incidentally while visiting his child, and found him suffering with what he termed "gouty bronchitis." For this he had confined himself to bed. Two days subsequent he had been attacked with severe pain in his right side, at the border of the ribs, which cut short respiration and made every abdominal movement unbearable. He had slight elevation of temperature, and somewhat quickened pulse. His diathesis made me consider this a development of rheumatism affecting the diaphragm. A tightly fastened girdle gave a measure of relief.

The following day, however, the true character was manifest—namely,

A DIAPHRAGMATIC PLEURISY,

while in the progress of the disease the friction-sounds of plastic effusion were heard over the lower part of the right pleura. In twenty-four hours these râles were obscured by serous effusion to the height of four inches. Considerable pain and tenderness remained in the right hypochondriac region over the extent of the liver.

The serous effusion quickly subsided, the serum disappearing in four days. At this time the patient complained of cramps in the right calf. His wife stated that the muscle bulged out in a knot the size of her fist. Taking her description as given, I did not inspect the leg or thigh, and attributed the cramps to the supine position enforced by the pleurisy.

One day later the complaint was of fixed pain in the calf, which suggested examination of the femoral triangle, and I found the evidences of adhesive phlebitis. The leg and thigh swelled enormously, but in twelve days returned to nearly the natural size. While suffering from the phlebitis in the thigh and leg there was a good deal of pelvic pain and soreness on the right side, attributed to the upward extension of the inflammation.

Two days after the onset of the phlebitis the patient began to suffer from hiccough; at first at intervals, then more constantly, and even during sleep. The hiccough

lasted five days; for the three latter days almost without intermission. The hiccough was painless, but annoyed the patient by its persistence. The last two days, besides the hiccough, as often as once in two hours attacks of

LARYNGISMUS STRIDULUS

occurred of a minute's duration. To relieve the hiccough many means were tried. The faradic current applied at the back and over the epigastrium for an hour at a time seemed to be useful. Chloral given in five-grain doses was early administered, but an attack of laryngismus stridulus occurring immediately after the exhibition of a dose so prejudiced the patient that he refused to take it. Morphine, hypodermically, gave comfort, though the hiccough persisted even when the patient slept. In five days these attacks passed off, both of hiccough and laryngismus.

"Coincidently with the relief from hiccough the patient's leg had so improved that he was allowed to sit in a reclining-chair. He still complained of the pain in the right side of the abdomen. Palpation and percussion could detect nothing abnormal, and auscultation gave no sign. The thickness of the abdominal fat would have obscured anything. The patient continued to mend gradually, though having shifting pains in various joints. All morphia had been suspended and only tonics given. He was sitting in the reclining-chair, and was reading the morning newspaper, when a look of faintness passed over his face and he seemed to be for a moment unconscious. A physician living opposite was summoned, who pronounced him dying. Stimulants, ammonia and brandy, were given without effect. When I reached the house with my partner, Dr. Montague Swift, I found Mr. A——'s pulse 160, his respiration 40, his hands cold, his face pale and anxious, with pinched nostrils and drawn mouth. He looked like a man suffering from internal hermorrhage, while his expression was that which we consider indicates abdominal suffering.

Supposing death imminent I sent for Dr. Thomas, who had previously seen him in consultation, and later for Dr. D. M. Stimson. We all thought he could not rally from the collapse in which we found him.

From 9 P.M. to 7 A.M. I sat by his chair giving him brandy and digitalin hypodermically, and brandy with ammonia by the mouth. His pulse during the night was for hours so feeble and rapid that I could not distinguish it at the worst, but at six o'clock it was 160, at seven 140, and from that hour its improvement was steady. There was at no time any fluttering or disturbed action of the heart other than extreme weakness. The aeration of the blood was perfect and there was no duskiness of countenance, as would have been the case had circulation through the lungs been impeded. The mind was clear; motility unimpaired. In fine, there was no indication of

EMBOLISM OF BRAIN, LUNGS, OR HEART.

In default of evident cause the family were told that gout had affected the heart—a statement plausible to them, but which at the time did not seem to me to really explain the symptoms presented. My own feeling was that there had been an internal rupture; perhaps a slow, leaking aneurism, which the patient's corpulency concealed. But the after-history seems to have proved the gout-theory correct. It was the gouty poison overpowering the heart in its action; not as rheumatism seizes on the organ, exciting acute inflammation, but by nerve-influence only.

From this seizure Mr. A—— steadily convalesced. He had more or less of joint-pains, but no severity of attack. His chief subsequent annoyance was a return of pain in the right side of the abdomen from the liver downward. A free purgative removed scybalous masses, and the pain measurably ceased. The purgative was a shot in the dark, as palpation could detect nothing through the thick abdominal walls.

Before this case came under my observation I had looked upon the phrases "gout of the stomach" and "gout of the heart" (as distinct from inflammations of these organs) as names used to satisfy a patient's friends, but really conveying a false pathological idea.

"Several years ago I had a patient in whom the rheumatic poison so affected the brain that she was delirious for days, and approached a comatose state, suddenly to be relieved by the transfer of inflammation to a knee-joint. But in this there was marked inflammation, and a subsidence of trouble in one part of the body with a transfer to another.

In the case of Mr. A——, in the light of its after-history, I feel inclined to attribute the symptoms—so grave that no one of the five physicians looked upon the patient as aught but a dying man—to the gouty poison, and to describe it as a layman would.

In pathology I supposed the poison exerted itself on the organic nervous centres, as no sign of acute inflammatory trouble was manifest either then or afterward."

DR. HUDSON said it had not seemed to him to be proved that pure diaphragmatic pleurisy could be diagnosticated.

DR. C. L. DANA reported the results of his experience with

GASEOUS INJECTIONS IN THE TREATMENT OF PHTHISIS.

He began the treatment in the middle of February last, and had employed it for eight weeks. It was too soon to give definite conclusions, but his experience in the technique of the operation might, he thought, be of some interest.

A brief synopsis of the reports on the treatment so far made by Bergeon, in August, 1886, and later by Cornil, Morel, Dujardin-Beaumetz, Bennett, and Hamon and Fougeray, was given.

Dr. Dana had given the injections in a number of cases, but had systematically followed them up in only three. These were all cases of catarrhal phthisis in the third stage. They were all men in age ranging from thirty to forty. They had all three decidedly improved since the treatment began. There was a gain in flesh and strength, with some diminution in cough and expectoration. The night-sweats were stopped in two cases, and the fever almost or entirely disappeared in all. In one case the improvement did not occur until two weeks after the injections were begun. Very similar improvements have been observed in other cases coming to the hospital.

The apparatus used was very simple. At first he used bisulphide of carbon vapor. The carbonic-acid gas was procured from a soda-water manufacturer. It was washed, and special instructions given to have it pure. It was bought compressed in cylinders. This was passed into a rubber bag holding about two gallons. From the bag the gas was passed through a glass cylinder containing a teaspoonful of bisulphide of carbon poured upon cotton. From the cylinder it passed through a tube and into the rectum. About a gallon of gas was injected at a time—at first once, then twice daily. The patient lies on the back, and the bowels are rubbed and kneaded during the operation, which lasts from twenty to thirty minutes.

The gas was smelt in the breath of one patient, but not in that of the others. It caused no pain, but did produce dizziness, and in one case nausea.

The results of the use of the sulphide were not very satisfactory, and after two weeks' trial pint-bottles of Sharon mineral water were substituted. This water, Dr. Dana found, corresponded fairly well in composition with the Eaux Bonnes water used by Dr. Bergeon. One bottle was sufficient to medicate about two gallons of gas. The three patients had been treated in this way for nearly six weeks, and as stated, they had all improved, one of them very decidedly. The gas was smelt in the breath and tasted by the patients. The speaker

thought that the results, though encouraging, were by no means brilliant, and believed that so far as facts at present go, we had better means of treating phthisis than by gaseous injections.

The composition of the Eaux Bonnes water used by Bergeon was given, as follows:

Bisulphide of soda	0.01150
Monosulphide of soda	0.00280
Hyposulphite of soda	0.00035
Carbonate of soda	0.00650
Silicate of soda	0.09520
Phosphate of soda	0.00070
Sulphate of soda	0.07637
Sulphate of lime	0.09975
Sulphate of potass	0.01353
Chloride of soda	0.10997
Chloride of lithias	0.02750
Organic matter	0.05707
Total solids	0.51180
Free H. S	0.00190

Dr. Robinson had tried gaseous injections in four or five cases in Charity Hospital. He used for mineral water that of the Blue Sick Spring, Ky.; but this was abandoned and the bisulphide of carbon substituted, and the patients were benefited somewhat so far as symptoms were concerned. There was a decided odor of the breath soon after an injection was given. In one case so much dyspnœa was produced that it became necessary to give up the plan of treatment. He did not notice that any special amount of pain was produced by the injections.

Dr. Hudson had made some inquiries concerning the gaseous injections made in cases of phthisis in Philadelphia, and had learned that they were in some cases administered by a druggist, the patients being walking patients, and it occurred to him that probably as much benefit came from the exercise, etc., as from the sulphuretted hydrogen which they received.

The Society then went into executive session.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, April 25, 1887.

Laurence Johnson, M.D., President, in the Chair.

Dr. L. Bolton Bangs read a paper (see p. 513) entitled

EXTERNAL URETHROTOMY—A PLEA FOR ITS EARLY PERFORMANCE IN MINOR TRAUMATISMS OF THE URETHRA.

The discussion was opened by Dr. F. N. Otis, who fully coincided in all that the author of the paper had said concerning the probable benefit to be derived from an early external operation in the cases of urethral injury under consideration. The most difficult cases came from traumatism, difficult from the very beginning throughout. Even the most thorough operations were apt to be followed by urethral trouble.

But when the tissues were in a comparatively good condition, and the canal was kept patent, the urethra probably could be left as well off as it was before the injury.

With regard to cases in which

DEPARTURE OF THE URETHRA THROUGH FOLLICULAR ULCERATION

had occurred, they were of importance to the surgeon, especially in their early recognition. Not long ago he saw in one of the foreign journals an account of a hospital case in which there was a perineal inflammatory swelling, not attended by closure of the urethra. The catheter was passed without difficulty, and it was regarded as a case of perineal abscess not connected with the urethra, and poultices were applied, the surgeon declining to open it at that time. Extravasation of urine, however, took place and the patient died. Dr. Otis thought that not too much could be said in favor of an early external operation in such cases as that. The operation was a simple one, especially where there was no displacement of the urethra, and the patient has thereby been saved at once from the danger of extravasation of urine.

It was deceptive to suppose that, where a comparatively large-sized stricture exists, the urethra could not be ruptured. He thought that probably nineteen-twentieths of the cases of perineal swelling were due to this cause, and that the earlier they were operated on the better it would be for the patient. As to the safety of external urethrotomy, he fully agreed with the author of the paper.

Dr. E. L. Keyes had nothing to say in opposition to the views advanced by Dr. Bangs. He not only indorsed them, but wished to add all that the weight of his experience could add to the view that in cases of

MINOR TRAUMATISM OF THE URETHRA,

at least in the curved portion, the patient should be immediately subjected to perineal urethrotomy; that is, in cases in which, after traumatism, there appeared, immediately or subsequently, evidence of advancing inflammation about the perineal urethra, the operation should be performed and free drainage established, provided no extra harm could be done to the patient by the procedure. He thought that the experience of all would favor a large open wound through which free drainage could take place, rather than treatment by dilatation or divulsion. He believed that this was true concerning any stricture which was not easily controlled by possibly the simplest of all methods, that of gradual dilatation.

Undoubtedly perineal urethrotomy was a somewhat formidable operation in "the older days," and it was still somewhat difficult and tedious where it must be done without a guide; but he could hardly conceive of an operation more simple than perineal urethrotomy upon a guide, and the after-effects were of the simplest kind. Of course, in cases of infiltration of urine, with sloughing and extensive disease of the tissues, the patients might die despite the incision.

Dr. Keyes also believed that

GRADUAL DILATATION IS FALLING INTO DISCREDIT

in the treatment of old strictures in this part of the urethra. The advisability of *divulsion*, he thought, had been nearly given up. *Internal urethrotomy*, in this region, according to his experience, was disastrous and dangerous. He was free to say that he should vastly prefer, in any kind of stricture in the deep urethra, the *external operation* to any other method of treatment; for, in healthy subjects, the external method was nearly or entirely devoid of danger.

Dr. C. McBurney was glad to hear that the ideas set forth by the author of the paper were gaining ground among surgeons. He regarded the operation of external urethrotomy, for traumatism of any moment at all, as undoubtedly an exceedingly good one, and because it was

THE ONLY MEANS OF AVOIDING DANGERS WHICH WERE IMMEDIATE AND GREAT.

Up to within a very short time the tendency had been to neglect to interfere with a urethra that presented on the outside the outline of integrity. The dangers of internal urethrotomy in the deep urethra were well recognized, and it was probable that when a man received a kick in the perineum, for example, he was in a worse condition than the man who had the condition which had received the internal operation.

Besides, secondary dangers were avoided by the external operation performed *early*, before infiltration or suppuration had taken place, and before sinuses had formed in various directions. It was better to anticipate the dangers than to wait until they came.

With reference to the operation itself, perhaps something might be said which would mitigate its terrors to the patient and also to the surgeon. The operation was to provide for *perfect drainage from the bladder*, and nothing more. External urethrotomy, to him, did not mean

division of the stricture from the outside. Therefore it was unnecessary to divide the whole of the stricture. The opening could be made very small, without hemorrhage of account, or involving any important structures, and it would heal with the greatest rapidity and without any danger. A small operation performed behind or in the middle of the stricture in the deeper portion of the urethra gave as good results as a full incision made throughout the entire length of the stricture.

Dr. McBurney believed, however, that there were cases in which external urethrotomy was not required. In a case in which there was no evidence of laceration beyond the escape of a few drops of blood, no tumefaction, no infiltration of blood, where it was perfectly easy to pass a large instrument, and also, and more important, where it was perfectly easy to introduce a *small* instrument, meaning that there was rupture of only small superficial vessels, he would not perform external urethrotomy. He would pass a large, soft instrument, after both a large and small instrument had passed easily without detecting lacerated tissue, evacuate the bladder systematically, wash it out after each urination, and in a certain number of cases the operation could properly be avoided. But it was difficult to define this class more accurately.

Dr. Bangs, in closing the discussion, expressed his gratification at the unanimity of opinion with regard to the best method of treating these cases. He then related a case that came under his observation since the paper was written. At present it was difficult to classify all these cases, but he believed that when traumatism was present to the degree he had mentioned there was only one proper mode of treatment, which was to perform external urethrotomy.

Dr. George Thomas Jackson then read a paper (see p. 509) entitled

BALDNESS—WHAT CAN WE DO FOR IT?

Dr. George Henry Fox said that in some cases local treatment alone sufficed to remove the abnormal condition of the scalp on which the alopecia depended. In other cases there was a good condition of the scalp, and baldness occurred in consequence of other causes, such as exhaustion of the nervous system, etc., and in those cases a general tonic and hygienic treatment might produce restoration of the hair, or arrest its falling.

Then there were cases of *inevitable* baldness, beginning as a small spot upon the vertex, or going up from the forehead, and in which the only thing which could be done was

TO MAKE THE BEST OF IT.

He doubted whether any style of hat had ever had anything to do with causing baldness. In very many cases the cause had not been explained.

Dr. W. M. Carpenter asked Dr. Fox and Dr. Jackson to express their opinions concerning the utility of either cutting the hair short or shaving the head in cases of falling of the hair after typhoid fever, for example.

The President took exception to Dr. Fox's statement with reference to stiff hats not being a cause of baldness, and expressed the belief, firmly, that the wearing of stiff hats had a great deal to do with the occurrence of baldness.

Dr. Fox doubted whether baldness was any more common now than it was before stiff hats were worn.

With regard to cutting the hair or shaving the scalp after fevers, unless there were special reasons for so doing, he believed that, in the majority of cases, where the hair could be attended to properly, it had better be let alone, and that its growth would be longer and stronger than it would be after cutting or shaving.

Dr. Jackson agreed with Dr. Fox with reference to cutting the hair or shaving the head after fevers. He would also remark that the English had always worn stiff hats, and it had not been shown that they were particularly the subjects of baldness.

The Society then adjourned.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, April 5, 1887.

C. L. Dana, M.D., President, in the Chair.

Dr. T. S. Robertson read a paper (see p. 517) on the use of

ANTIPYRINE IN MIGRAINE, PYREXIA, ETC.

Dr. E. C. Spitzka had seen antipyrine once act magically in relieving the headache of a cerebral tumor. On repetition of the dose, however, the remedy failed.

Dr. B. Sachs had been using antipyrine for a considerable time in headaches and migraine, and he had found it to act very satisfactorily.

Dr. W. R. Birdsall and Dr. R. F. Weir

REPORTED A CASE OF SARCOMA OF THE BRAIN (OCCIPITAL LOBE), CAUSING HEMIANOPSIA, REMOVED BY OPERATION.

Dr. Birdsall gave the history of the case, of which the following is an abstract: The patient, a Hebrew, aged forty-two, first came under his observation, October 16, 1886. He had always been healthy, until the summer of 1886. He denied injury to the head or venereal disease. In August, 1886, he observed for the first time unsteadiness of gait, and had a severe attack of vomiting. Soon after, diplopia for distance, and increased awkwardness in walking were observed; also a disagreeable sensation, akin to numbness, in the right leg, hand, and shoulder, but not in the face. This and the diplopia were transitory. Headache, usually frontal, was present occasionally, but never severe. October 7, 1886, he consulted Dr. F. C. Seguin, who made a diagnosis of tumor of nasal aspect of right occipital lobe, involving, primarily, the cinereus, extending downward toward the tentorium cerebelli, and perhaps also upward toward the para-central lobule (leg-centre). Treatment: Large increasing doses of potassium iodide.

From January to July, 1886, his diplopia disappeared, and never returned; his gait improved somewhat. In October, 1886, Dr. Birdsall found double optic neuritis, most marked in left eye; left pupil somewhat larger than right; no diplopia; no ocular paresis evident. His movements were clumsy rather than ataxic, at times being accurate, at others wide of the mark, especially in left extremities; gait slow and uncertain. There was frequent expectoration of a viscid saliva. Left hemianopsia, Dr. Birdsall thought, could be accounted for only by a destructive lesion in the neighborhood of the gyrus cinereus of the right occipital lobe. The locomotory disturbances appeared to him to be due to pressure-effects of a tumor on structures below the tentorium; thus implying a growth of considerable size. His disturbance of equilibrium continued to increase in a very irregular manner. His intellect was not impaired. His family observed no change in his character or disposition. He was extremely uncomfortable mentally. An operation was proposed in February, 1887.

The operation was performed by Dr. Weir. Regarding the tumor, Dr. Birdsall said it was of so large size, so much of the occipital lobe was compressed by it, that the case was of little value for determining the limitation of the visual area in the occipital lobe. The growth was a sarcoma, originating in the meningeal structures, producing destruction of the cerebral tissues by pressure alone. Absence of severe headache should be noted, as it is usually a prominent symptom of tumors involving the meninges. One of the most important lessons that the study of cerebral tumors taught was, that growths remaining limited to the meninges may attain a large size before disturbing the function of neighboring parts of the brain. In these cases regions away from the tumor may give signs of importance before those in contact with the tumor. The extreme fatality of intracranial neoplasms was high warrant for taking an extreme surgical risk. The co-operation of neurological science and surgical art, in

the present state of each, could hardly fail to build up an experience which would in some cases save life that would otherwise be lost.

Dr. Weir described

THE OPERATION,

which was performed March 9, 1887. Special antiseptic precautions, prior to and during the operation, were taken. The periosteum was raised, two openings were made with the trephine, the first one inch above the occipital protuberance and the same distance from the median line; the other immediately above. The openings were joined, and enlarged by the rongeur forceps to two and three-fourths by two and one-fourth inches. The dura mater was divided two-thirds the extent of the bone-opening, its retained attachment being toward the median line. The tumor was at once recognized and enucleated. It was necessary, on account of its large size, to incise it, and press out some of its substance before it could be completely detached and removed through the opening. A great deal of venous bleeding took place, and sponges were stuffed in for temporary pressure. The cavity was inspected by the electric light, and showed that a great amount of pressure had been exerted upon the brain; the falx was crowded to the left of the median line; the tentorium was depressed to a horizontal line. The tumor weighed five and one-fourth ounces. It measured three and one-fourth by two and three-fourths by two and one-half inches. One of the bleeding points was found to be in the region of the straight sinus, not free enough to be from that vein, but probably from the pedicle of the tumor; the other, apparently arterial, probably from a terminal branch of the posterior cerebral artery. The flow from each was readily checked by direct pressure, and it was determined to control them by packing the cavity with iodoform gauze. The dura mater was partly united over the gauze by loose sutures. The operation was well borne until the final enucleation of the tumor, when the pulse fell, apparently from loss of blood. Some hours afterward slight diverging strabismus of the left eye was noticed; blood-stain appeared through the dressings; the pulse was weak; stimulants were given; the patient was restless. At night transfusion of a saline solution was made, with temporary improvement, and the dressings were removed to control hemorrhage, which was seen to be taking place in a small stream, but the pulse again gave out, and nothing further could be done than reapply pressure in the supposed direction of the hemorrhage. Death occurred at 2 A.M. An autopsy was not allowed, but in the lower part of the brain-cavity was seen a large collection of coagulated blood.

Dr. Weir said that, in another case where the hemorrhage was from vessels too deeply situated to apply a ligature, he would control it by leaving on clamp-forceps, to be removed after a period of twenty-four or forty-eight hours. The opening, although large, was not sufficiently large to enable him to remove the tumor entire. It was intended to adopt Macewen's method, and employ bone-grafts.

Dr. Weir had recently

REPLACED THE PIECES OF BONE

removed by the trephine in a case of epilepsy, the opening being nearly two and one-half by three inches, and now, about seven weeks after the operation, the wounds had healed save one, and the bones were felt to be solid, and were painless. Brief reference to the cases of tumors of the brain for which operations had been performed were made.

REPORT OF A CASE OF CYST OF THE BRAIN, WITH OPERATION.

Dr. Graeme M. Hammond related the case. The patient, a married woman, complained of severe pain an inch above the right ear, and had left hemiplegia. At the time her symptoms began she was about twenty-nine years of age; she had had four children; during the progress of her disease she had a fifth child. All were strong and well. Her sickness lasted about two years and a half. It commenced by sudden loss of consciousness, and convulsions limited to the left side. The left side of the face became, and remained, paralyzed. About a year later she noticed gradual loss of power in the left arm; things dropped from the hand. At the end of another year the left arm was completely paralyzed. She then noticed increasing weakness in the left leg. When Dr. Hammond first saw her she was able to stand, and walk slowly. While the paralysis was extending she had four or five epileptic seizures, confined to the left side. Headache developed about the time the legs became affected, grew more constant, and was described as agonizing.

She denied syphilis. Physical examination showed loss of motion on the left side of the face, tongue, and soft velum; of the left arm, and partial loss of motion in the left leg. There was no disturbance of sensibility of any kind. The reflexes were exaggerated on both sides. Sight, hearing, smell, and taste were normal. Choked disk on both sides was observed at a subsequent examination.

Under treatment the headache was controlled to a considerable extent. Dr. Hammond's diagnosis was probable cerebral tumor, involving the cortical or subcortical substance of the motor centres. An operation was refused. The patient grew worse until March 20, 1887, when her husband asked that the operation be performed. Dr. Spitzka then saw the patient with him, and made two examinations. He rather coincided in the diagnosis. The operation was performed on the Wednesday previous. Dr. M. Josiah Roberts assisted at the operation, removing the portion of skull by his electro-osteotome. Four buttons were removed by the electro-trephine; these were connected by straight lines made with the circular saw. The diameter of the opening was over two inches. A crucial incision was made through the dura. A hypodermatic needle was introduced in different directions, but no fluid was withdrawn. The dura was closed, a drainage-tube was introduced, the skin-flaps were sewed up, and the patient was put to bed. She lived only twenty-one hours, remaining unconscious after the operation. Prior to the operation she had become completely paralyzed in the left lower limb, she had delusions and hallucinations, she talked incoherently, and bed-sores developed.

The autopsy showed little hernial protrusion at the wound; the cortical substance here was thin. Incision through the motor region revealed three cysts in a line deep in the white substance. The fluid in the cysts had been only partially examined; it was serum, and contained broken-down brain-substance. The cysts were close together and in a position to affect the face, arm, and leg-centres. He could not explain why the syringe failed to bring forth fluid unless it was that the cysts were too deeply situated, or the needle passed between them. He added to the clinical history that the head was drawn to the right side the last three days of life.

DISCUSSION.

Dr. E. C. Seguin was partly responsible for the operation in the first case, but it seemed the patient would not live more than two or three months without it. He expected to find a large tumor, but was somewhat surprised to see it encapsulated and non-parenchymatous. During the early history of the case the symptoms pointed to destruction of brain-tissue.

Dr. E. C. Spitzka, referring to the case reported by Dr. Birdsall and Dr. Weir, said that an artery, large enough to cause fatal hemorrhage, entered the gray and white substance of the right occipital lobe. It had been overlooked in many text-books.

Dr. Roberts explained how the circular saw could be

used without injury to the brain, and described the operation of the electro-osteotome.

Dr. Starr suggested the desirability of an analysis of reported cases of cerebral tumors, for the purpose of determining their rapidity of growth and size.

Dr. R. L. Parsons read a paper entitled

NOMENCLATURE IN PSYCHIATRY: "MONOMANIA" OR "OLIGOMANIA.

The reader advocated the use of the term "oligomania" in place of "paranoia," primary monomania, partial insanity. Discussion was postponed.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 24 to April 30, 1887.

Woodruff, Charles E., First Lieutenant and Assistant Surgeon (recently appointed). Ordered for duty at Fort Wayne, Mich. S. O. 96, A. G. O., April 26, 1887.

Official List of Changes in the Medical Corps of the United States Navy for the week ending April 30, 1887.

Atlee, L. W., Assistant Surgeon. Ordered to the Receiving Ship Vermont.

Biddle, Clement, Passed Assistant Surgeon. Detached from the Naval Academy and ordered to Marine Rendezvous, Philadelphia, Pa.

Ashbridge, Richard, Passed Assistant Surgeon. Ordered to the Naval Academy.

Hudson, A., Medical Inspector. Ordered to the U. S. Ship Trenton.

Hibbett, C. T., Passed Assistant Surgeon. Ordered to the U. S. Ship Trenton.

Decker, Corbin J., Assistant Surgeon. Detached from the Receiving Ship St. Louis and ordered to the U. S. Ship Trenton.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 30, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	5	2
Scarlet fever	55	14
Cerebro-spinal meningitis	1	1
Measles	69	5
Diphtheria	120	51
Small-pox	5	2
Yellow fever	0	0

Aniline Inhalations in Phthisis.—Professor Kremiansky's method (*Journal*, p. 579, March 12, 1887) was recently tried by Dr. Nesteroff, of Moscow (*Russkaia Meditzina*, p. 151, No. viii., 1887), in the case of a lady suffering from consumption, whose condition was not at all such as to cause immediate apprehension; in fact, she was about to start for a southern health-resort. Under inhalations of aniline dissolved in oleum gaultheriæ, the patient's state grew steadily worse; and after two weeks of the aniline treatment she died. Dr. Nesteroff emphatically declares that he will never venture to repeat the experiment; he maintains that the method is not only useless but directly injurious.

The New "Specific" for Diabetes.—Dr. Martineau gives full details in the last number of the *Annales Médico-Chirurgicales* of the treatment advised by him in diabetes. It was in consultation with the late Professor Rouget that he learned the formula which he now publishes with so much confidence. The patient in question had been the subject of diabetes for some years, and was suffering at the time from cerebral hemorrhage. Dr. Rouget proposed that they should not modify his diet in any way beyond restricting in a slight degree the use of farinaceous food, fruits, and sugar, and that he should drink during meals, and in the intervals of thirst, arsenicated lithia water, prepared as follows: In the upper part of a Briet apparatus of one litre for making aërated water were to be introduced 20 ctg. of carbonate of lithia, and a tablespoonful of the following solution: Arseniate of soda, 20 ctg.; distilled water, 500 gm. This water to be drunk at meals mixed with wine, and the contents of the recipient to last for three meals.

The Danger of Hypodermatic Injections of Morphine in the Treatment of Strangulated Hernia.—Dr. Routier had operated twice for strangulated umbilical hernia; the first operation was performed twelve hours after the strangulation and was a perfect success. He was not called to the second until five days after the onset of the trouble, and found gangrenous points scattered along about thirty inches of intestine; he resected the entire affected part, but the patient soon died. This patient had been treated with injections of morphine, which had relieved the pain and arrested the symptoms, and thus caused the grave error of permitting fatal temporization. He has ascertained that the use of injections of morphine is very common in strangulated hernia. Various cases have been published in favor of this treatment, but none are convincing; it is impossible to understand how morphine can favor spontaneous reduction; in that case it would be necessary for the strangulation always to lie in the ring and for the relaxation of the muscles to have an influence upon it, which is doubtful. Nothing, then, is further from being proven than the good results of this treatment; on the contrary, its dangers are self-evident, since, by diminishing pain and vomiting, it permits temporization, which is always exceedingly dangerous, for the operation is acknowledged to be the more dangerous as it is delayed. The treatment of strangulated hernia by morphine should be very energetically rejected, and it should be held as an axiom that a patient with strangulated hernia should not be left until relieved. —*Annals of Surgery*, April, 1887.

Turpentine Stupes for Tonsillitis.—Dr. Longstreth recently showed the class at the Pennsylvania Hospital some cases of tonsillitis which had simply been treated by applying turpentine stupes to the neck, with gratifying results.—*Col. and Clin. Record.*

Belladonna in Prurigo Senilis.—Belladonna given internally will often give very satisfactory results in prurigo senilis. It may be given with nux vomica as follows: ℞. Extract. nucis vomicæ, extract. belladonnæ, āā, gr. ¼. Ft. pil.—Sig.: Take morning and evening.—*Col. and Clin. Record.*

Infantile Constipation.—A very successful remedy for this is podophyllin, in small doses; iridin may be combined with it with good effect. Make a tincture of the following: Podophyll. resin, gr. viij.; iridin, gr. v.; spt. ammon. arom., ʒ j. Digest for several days, and filter. From one to two drops of this may be given at bedtime on a small piece of loaf-sugar, or the dose may be combined in mixture along with syrup of orange. This is the dose for a child of one year and under.

"Disease" is the name given to one of the swift yachts of the Burlington Ice Yacht Club. The Disease must be a kind of running disorder—possibly mastitis.

The Medical Record

DIGITAL EXPLORATION OF THE KIDNEY WITH REPORT OF THREE CASES.[1]

BY WILLIAM T. BELFIELD, M.D.,

GENITO-URINARY SURGEON TO COOK COUNTY HOSPITAL; PROFESSOR OF GENITO-URINARY DISEASES, CHICAGO POLYCLINIC.

OF some two hundred and fifty cases of nephrectomy heretofore reported, about forty-four per cent. have died from the effects of the operation. The chief causes of death have been: 1, Shock (forty-two per cent. of the fatal cases); 2, uræmia (fourteen per cent.); 3, peritonitis (twenty-one per cent.). Improvement in the results of renal surgery seems therefore to require means for the avoidance of these three chief dangers.

The chances of fatal shock are decreased by early operation, before the patient becomes exhausted and the destruction of kidney-tissue extensive. This self-evident proposition is illustrated by the fact that while about eighteen per cent. of all (250) reported nephrectomies have died of shock, yet after twenty-four excisions of sound kidneys in healthy persons—removed for wounds of the loin or ureter, mobility, etc., not a single death occurred from shock.

The greatest obstacle to the early surgical treatment of renal lesions has been *faulty diagnosis*. Such cases are frequently regarded as lumbago, sciatica, hip-joint disease, Bright's disease, and (especially) cystitis, for a long time before the true seat of the lesion is detected or even suspected.[2] The symptoms commonly ascribed to cystitis may be also produced by pyelitis; and as cystitis is still too often regarded as an entity, a disease—instead of a mere symptom requiring explanation—the patient is treated for "chronic cystitis." Finally, months or years later, a lumbar swelling or other symptom reveals the renal origin of the difficulty.[3] Meanwhile the patient has become so enfeebled that he succumbs to the shock of an operation that could have been safely borne at an earlier period. Early exploration of the kidney—a relatively safe operation—has in many cases not only solved a perplexing problem in diagnosis, but also, by drainage of the pelvis, has relieved a difficulty which at a later stage would have required nephrectomy—a formidable operation. Moreover, a preliminary drainage has been shown to be a valuable factor in diminishing mortality after nephrectomy; thus, of 73 nephrectomies for suppurative lesions collected by Gross, 12 were made after previous exploration, with but 1 death; of the remaining 61—without previous nephrectomy—31 died.

Uræmia rarely occurs after any renal operation, provided the second kidney be present and in healthy condition. While commonly associated with nephrectomy, one of the cases described shows that uræmia may be inevitable after simple nephrotomy; hence a necessary preliminary to any renal operation should be an attempt to ascertain the functional condition of the opposite kidney. In the female this can often be accomplished by catheterizing the ureter, after Pawlik's method; in the male, probably the best (though still an uncertain) means is Silbermann's instrument for compressing one ureter. The statement that the abdominal incision, by permitting palpation of the opposite kidney, obviates the possibility of uræmia, is fallacious; for in many cases kidneys which are indistinguishable by the finger, or even by the eye, from normal organs, are extensively invaded by disease—inflammatory, tuberculous, or calculous. The pair of kidneys exhibited by Dr. Steele this evening are signal examples—normal in size, contour, and consistence, yet each extensively tuberculous; palpation through an abdominal incision could have detected nothing abnormal in either of these kidneys. Certain gross renal lesions could doubtless be so detected, though at greatly increased risk.

To summarize: 1. Surgical affections of the kidney are frequently long masked by symptoms of cystitis, etc.; differential diagnosis may be practically impossible without palpation of the kidney.

2. Digital exploration of the kidney through a lumbar incision is, with proper precautions, almost free from danger, comparing favorably with perineal exploration of the bladder.

3. This operation, performed at an early period, may arrest a morbid process which would otherwise require nephrectomy; even it it secure no other immediate result than accurate diagnosis, it diminishes the danger from subsequent nephrectomy.

4. Before undertaking to incise the pelvis, the functional activity of the other kidney should be demonstrated by examination of its secretion.

S. M.——, widow, aged twenty-six, has long suffered from dyspepsia; for a year past has been much troubled with headache, pain in loins and left thigh; menstrual intervals were shortened to two or three weeks. In March, 1886, urination became unduly frequent and often painful; pus and sometimes blood appeared in the urine. In June began to have nausea and vomiting; also disturbances of vision, spots before the eyes, etc. Pain, of varying intensity, became constant in back, abdomen, and left thigh; has been confined to bed ever since. On admission in October she is emaciated and very feeble; requires morphine constantly; tenderness over both kidneys, especially left; no swelling nor logy feeling. Urination every half-hour or oftener, the act accompanied with severe pain at the bladder-neck. Urine varied from nine to twenty-seven ounces daily, and contained much blood, pus, and numerous sharp uric-acid crystals, often arranged in rosettes and surrounded with pus-corpuscles. The right ureter was catheterized, and urine found free from pus and blood.

November 29, 1886, the left kidney was exposed by transverse lumbar incision; to the eye and the finger it was normal; needles passed into the pelvis detected no foreign body. The pelvis was thereupon opened by cautery and explored with the finger; the mucous membrane was rough and ulcerated, and numerous clots of pus were evacuated. Aside from persistent vomiting for a few days, recovery ensued without notable interruption; the lumbar fistula was closed on the twenty-first day. The patient has since been free from her former symptoms and is regaining flesh and strength; the urine is free from pus and blood.

The case presented several interesting features.

---

[1] Read before the Chicago Medical Society, March 7, 1887.

[2] An English surgeon recently removed both ovaries, at two operations, without relief to symptoms which disappeared at once after the extraction of a renal calculus by another operator.

[3] This masking of pyelitis by bladder-symptoms is particularly common in cases of primary renal tuberculosis, in which lumbar pain is rarely pronounced unless the ureter becomes obstructed by clots of pus. As five such cases have come under my observation within six months, I suspect that they are less rare than is generally supposed.

Though the symptoms—hemorrhages, suppression of urine, and extreme prostration—were such as might be expected from calculi in both kidneys, yet they were induced by aggregations of uric-acid crystals—the largest smaller than pinheads—in *one* pelvis. The menstrual interval was shortened, as the disorder became aggravated, to three, and then two weeks; after the operative relief they were again lengthened to four weeks. Especially noteworthy was the direct sequence of the urinary upon the digestive derangement. Several times during convalescence symptoms of indigestion—gastric distress and distention, belching of gas, etc.—occurred, and were invariably followed within a few days by pain over the kidney, irritability of the bladder, and the appearance of sharp uric-acid crystals and some pus in the urine; with the subsidence of the digestive disturbances the urinary function again became normal.

George F——, aged thirty, was struck by a cable-car, November 28, 1886, sustaining a laceration of the hand and various bruises. The patient had left his bed, though still sore from the contusions, when, December 11, after straining at stool, he passed a large quantity of bright blood with the urine, and had severe pain in both loins; temperature, 102. Ergot, gallic acid, and opium internally, ice locally, and absolute rest, were ordered. The hemorrhage ceased in seventy-two hours, but pain and tenderness over right kidney and pyuria persisted with varying intensity and same temperature. December 21st, he had several slight chills, followed by profuse sweats, fever, headache and vomiting; deep inspiration caused great pain in right loin.

December 22, a transverse lumbar incision was made for exploration of right kidney; there was found extensive adhesive inflammation, matting together the colon, peritoneum, and peri-renal fat; extravasated blood under the kidney-capsule; a laceration in the posterior surface of the kidney, extending transversely from the lower insertion of the pelvis about an inch into the renal substance; opposite this fissure were some blood-clots and about half an ounce of clear fluid. As the location prevented stitching of the capsule, drainage-tubes were inserted to the point of laceration. For several days the temperature remained high, and pus and urine were profusely discharged; then improvement was noted; the wound was healed in a month and the patient was discharged well a week later.

C. L——, aged forty-eight, enjoyed excellent health until two years ago, since which time he has suffered from gradually increasing frequency and pain in urination; urine has contained pus, and sometimes a little blood. A year ago he passed two small calculi, as large as buckshot. During last three months has had occasionally some pain in left groin and testicle, lasting some hours—evidently mild renal colic. Has been treated for Bright's disease and cystitis. When placed under my care, January 5, 1887, he was rather emaciated, urinating every half-hour, with pain in bladder and glans penis; urine alkaline, thirty to forty ounces daily, containing much pus and some blood-corpuscles; some tenderness on firm pressure over left kidney, none over right. There was evidently pyelitis on left side, of either calculous or tuberculous origin; a single examination of the pus revealed no bacilli.

January 26th, left kidney was exposed by lumbar incision; it was found to be above average size; at the junction of pelvis and ureter was a hard mass. To determine its nature the kidney was incised; the finger in the pelvis found this cavity dilated, and at a few points ulcerated; the hard mass consisted of thickened tissues, partly occluding the ureter. As the disease was evidently tuberculous and the condition of the opposite kidney unknown (though suspicious in view of the enlargement of the left), extirpation was deemed injudicious. The patient was not depressed by the operation, and was sitting up in bed on the third day. On the fifth day, however, the urine was tinged with blood, and decreased in amount; the usual symptoms of uræmia followed, ending in death from that cause on the eleventh day. A partial autopsy showed the left (explored) kidney slightly tuberculous and deeply congested; the right kidney extensively tuberculous; bladder and prostate normal.

In this case there was nothing in the history or physical signs to indicate disease of the right kidney; since this is the rule in tubercular, and not infrequent in calculous disease of the pelvis, the case teaches the necessity of examining the urine from the opposite kidney before opening the pelvis of the one under suspicion. The exciting cause of the uræmia was apparently not the slight wound in the substance of the working kidney, but the intense congestion following the sudden relief of habitual pressure in the distended pelvis; the case was, in fact, identical with those in which diminution of urine, renal hemorrhage, or even uræmia, follows a few days after the first catheterization in cases of enlarged prostate, etc., where the accustomed distention of bladder, ureters, and pelves is suddenly relieved—improperly termed "urethral" or "catheter fever."

THE CLAIM OF MORAL INSANITY IN ITS MEDICO-LEGAL ASPECTS.[1]

By JAMES HENDRIE LLOYD, A.M., M.D.,

INSTRUCTOR IN ELECTRO-THERAPEUTICS IN THE UNIVERSITY OF PENNSYLVANIA.

In the experience of the writer, which is largely based upon nearly three hundred cases of insanity, it has not been his fortune to see one case which answers to the description, given in the books, of moral insanity. The three hundred cases cited have all been studied with care for the purpose, chiefly, of certifying, under the law, to their mental condition. In most of them the antecedent history was attainable, and in many of them any unusual developments in their subsequent careers would probably have reached the writer's knowledge. These cases presented, I believe, all the recognized forms of insanity as laid down in all the classifications now in fashion. They came from all grades of society; some were committed to pauper asylums, some to the most select private and public institutions, and a few to an institution for feeble-minded children. They were representative of a very large insane population, because the writer formerly had the advantage of certifying almost all insane paupers of Philadelphia, and continues, through the kindness of the medical officers, to make out certificates of insanity for many patients coming from other States to asylums in or near this city, as well as to be retained not infrequently in private consultation for the same purpose. Records of all these cases have been preserved, and especially interesting features or unusual symptoms have been noted. In addition to the above cases the writer has studied a large number of brain cases during five years' attendance upon the Nervous Dispensary of the University Hospital. In an experience of this kind it could not be expected that no evidence of moral obtuseness or obliquity had been observed; far from this, the most diverse and extraordinary perversions of the moral ideas have been noted, just as perversions of all other cerebral activities have been recorded, but no case has been found in which that pure and simple dislocation of the moral nature existed, without lesion of the understanding, which we are led to believe by some writers is a not unusual form of insanity—especially of criminal insanity. It will be, therefore, the object, in part, of this paper, to compare briefly some of these cases of the writer with a very few of the most important cases mentioned by some of the most prominent writers who have described moral insanity.

I conceive this subject to have importance in two aspects. It has importance, first, to the medical nosolo-

[1] Read before the Philadelphia Medical Jurisprudence Society, April 12, 1887.

gist, or him who classifies and describes disease. It has still more importance to the medical jurist, or him who studies the actual legal relations of disease. With the first the subject is apt to degenerate into a mere quibble about *terms*. To the latter it presents itself as the most responsible question of *fact*. It thus appears that a brief definition of terms is of primary importance, while later it will be appropriate to make a short clinical analysis of cases and draw from them their proper deductions in medico-legal science.

It is not my intention in this paper to indulge in metaphysical abstractions, but it is imperative at once to consider briefly certain terms and distinctions which are constantly applied to this subject by medical writers, and which terms they have indubitably borrowed from the metaphysicians and theoretical psychologists who have been for generations thrashing this ground over and over again to find little wheat and much chaff. According to most of these speculators the mind is divided into (1) the intellect, (2) the emotions, and (3) the will. The "mind" itself is regarded by some of them as something immaterial, individual, and distinct from the organic brain. Each of these *faculties* has come to be treated in most systems as though it were a distinct thing in itself, with its own peculiar functions and diseases, just as the heart is a distinct viscus of the body apart from the arm, which, in turn, has its own partial independence. That such a division may have facilitated the study of abstract psychology, and may even yet furnish many convenient terms and much smooth rhetoric for the medical nosologist, is not to be doubted, but I think I am not mistaken when I say that the distinction is an entirely arbitrary one, and that there has never been offered an iota of evidence in anatomy, physiology, or pathology that these so-called "faculties of the mind" are anything more than varying phases or modes of action of one identical substance—the cerebrum. So thoroughly engrafted upon medical science is this creed of the metaphysicians that our books abound with classical descriptions of "intellectual" insanity as apart from "emotional" insanity, and a disease of "the will" has even been depicted under the dreadful name of *abulimia*. This latter so-called disease I saw exhibited in a poor woman who was suffering with melancholia, and had been cruelly treated and deserted by her husband. She stood in a corner of the room; she apparently could not speak nor perform any ordinary action. She was certainly without will or the active manifestation of it; but who can doubt that her mind was overwhelmed with depressing and stupefying ideas in which her intellect and emotions were hopelessly jumbled? Another case has been recorded of a man who sat immobile for a long time, having apparently lost his metaphysical "will," but who was found to be harboring the delusion that his body was glass and his only safety was in rest. The last effort of this doctrinaire school seems to have been in the direction of the conscience, or moral nature. Some call the moral nature a part of the emotions, while others give it a distinct place in classification, and this has led to corresponding confusion in moral insanity. With some it is purely an "emotional" insanity, with others it is "instinctive," with others it is a sort of *abulimia*, or loss of will, as in the "impulsive" varieties, etc. It is thus seen that there is much looseness with confusion of terms here, which is always suggestive of a confusion of thought. It is also apparent to my mind that in the cases reported by these writers there has been no strict, searching analysis of symptoms, or else the symptoms have been put down with strong bias in favor of the artificial classification employed.

A few weeks since a man came to the writer in great distress of mind, and said that as he was shaving one day recently the thought suddenly occurred to him that he might cut his throat, or possibly his wife's throat. He could not account for the thought, and neither could he cast it off, but was constantly haunted by the fear that he would yet commit one or both of these terrible acts of violence. If this man were to commit these acts he would probably be called by some writers a case of *impulsive* or *motiveless* insanity, in which, according to their favorite theory, his intellect would not be affected. Now it seems to me that this patient had a so-called imperative conception, which was delusional in character, and that he was in fact in a state of mind not unlike the hypochondriac who is constantly terrorized by the dread of what may be. This imperative conception *is* his motive, and if he falls a victim to it he is insane. The act would be as *intellectual* as any brain-act.

The truth about the brain-hemispheres, as far as we know it, seems to be that they are the seat of a special, highly differentiated reflex act. That they are, in fact, highly organized and developed masses of nerve-substance—which have probably by a process of evolution grown from the likeness of one of the inferior ganglionic masses to their present huge proportions and superior dignity, and that they are in no way exempt from the law, governing all nerve-centres, that upon excitation alone from without there comes a reflex act from within. This is, in other words, the law that upon sensation comes reflection, and is practically what was taught by Locke and Condillac, long before the era of Charles Bell or Marshall Hall, which is a curious confirmation of the truth that philosophic insight has often gone before scientific inquiry to demonstrate a fact. This highly specialized reflex act goes under a great variety of names, and is called memory, thought, intellect, reason, meditation, imagination, passion, will, talent, genius, etc., according to the point of view taken by the outsider rather than because of any known anatomical or histological changes or differences which take place in the insider. In other words, this special act has been given a legion of names according to its many and various phases, while in itself it can always be reduced simply to the condition of a reflex act, *i.e.*, perception, comparison, and action. This specialized act of the cerebral masses was named, I believe by James Mill, *ideation;* and as doing away with the innumerable artificial terms of the pseudo-psychologists, and being applicable to every conceivable mental act, it is the one for which I think medical writers ought especially to be thankful. From whatever point of view we take the human mind (by which I mean the human brain) we see it always reducible to this one term; for whether it meditates upon the highest problems of destiny or is tossed (metaphorically) with the stormiest passions of love or hate, it is essentially in the process of comparison, leading from perception to action, which conjoint act is this special process called *ideation*. Its diverse *manners* of acting, according to the character of the external objects which excite it, do not alter the essential unity and individuality of this special act. And yet it is according to its various modes merely that the classical and artificial distinctions have been made, by which even yet some practical alienists endeavor to steer their course, instead of by a more rational study of the identical acts of the brain itself—whose confusion, exaltation, depression, perversion, or disorganization can alone constitute either a scientific or a legal insanity.

I have never yet seen in actual practice a case of so-called moral insanity, or read the descriptions of such in the books, that it has not seemed easy to me to detect the fallacy which ascribes to such cases a normal intellect amid the ruins of the shattered soul. The following case was seen in Moyamensing Jail some six years ago, and has once since made some stir in the newspapers. A. B—— had fallen from his horse in boyhood and injured his head. He had preserved fair brain-power, and when he grew up had learned a profession, at which he attempted, without success, to practise. But he had grown up, nevertheless, a crooked stick, and was regarded by acquaintances as odd, ugly dispositioned, unreliable, and a crank. Upon a superficial view he fulfilled to the letter

the rôle of a moral lunatic; in fact he did out-herod Herod, and was a much better specimen of his class than is usually reported. He lived comfortably at the expense of his unmarried sisters, and talked so well that persons associated with him for months and did not suspect his mental integrity. He was affable to strangers, but of such rude and hasty temper to his family as to cause them sometimes alarm lest he should assault them. At last he began to excite a disturbance in the family about his father's estate, which had been divided and settled equitably years before, and announced that he had been defrauded of his share. In order to bring his sisters to terms he deliberately began to malign the reputation of one of them—who was a most estimable wife and mother—and set up an atrocious scheme of blackmail. When this became unendurable his family had him committed to jail to keep the peace, and in jail I signed his certificate, with a brother physician, to send him to Norristown Asylum. On examination of this man I found he had little correct reasoning power on any subject in which especially his own interests and relations were concerned, and that his disgusting egotism had culminated in a series of delusions of persecution in which he was as fixed as the earth in its orbit. If this man's *intellect* was not affected, it must indeed have been of the metaphysical variety in a literal sense, and have kept out of sight far above the physics of Moyamensing Jail when I saw and examined him.

He who has read Pinel on "Insanity," and has also a taste for the romance of history, has no doubt been pleased to find that author's science so illustrated with the events of the French Revolution. That momentous period made many men mad, and Pinel gives us many glimpses into some of the most tragic, but least known, acts of that historic cataclysm. I doubt, however, if any event he describes is more instructive than the breaking of the September mobs into the Asylum of the Bicêtre, and the liberation by them of a moral lunatic. It was announced in Paris that the asylums were unjust prison-houses, wherein were incarcerated many victims of kingly and priestly oppression, under the pretence of insanity. They would liberate these unfortunates. When they ransacked the Bicêtre, this patient loudly proclaimed that he was sane and a victim of tyranny. The keeper said he a was lunatic without disturbance of intellect, but of very bad passions—but the keeper came near being killed for his unphilosophic remark. The mob released this patriot prisoner, and led him in triumph through the streets. "The sight of so many armed men, their loud and confused shouts, and their faces flushed with wine, roused the madman's fury. He seized the sabre of his next neighbor and wounded several of his liberators. Had he not been promptly mastered he would soon have avenged the cause of outraged humanity. The savage mob then thought proper to lead him back to his cell, and with shame and reluctance yielded to the voice of justice and experience."[1] Pinel described this case as an example of mania without delirium, and subsequent writers who rely upon him have mistaken him, I believe, in considering that he meant a purely *emotional* insanity. I think he meant a mania without fixed, systematized delusions, and if he were here to-night I do not believe that he would say that this madman of the Bicêtre had an undisturbed reason.

Dr. Prichard, of England, is usually credited with being the progenitor of the school who teach the doctrine of moral insanity, although Dr. Rush, of Philadelphia, clearly indicated the same psychological distinctions. Prichard records seventeen cases as illustrative of this class of patients, and as a superstructure can be no more secure than the foundation upon which it rests I will briefly call your attention to a very few of these frightful examples. One patient was a literary man who was married to a literary wife, and became so suspicious that the world would say his wife wrote his books that he refused to let her know what he was writing; he acquired strange habits, placing everything in a certain order whether in his own or in other people's rooms. He would run up and down his garden a certain number of times, spitting alternately on one side and the other in regular succession. He spent much time rolling up little pieces of writing-paper, which he used for cleaning his nose. He committed several acts of violence, argued in favor of suicide, and finally drowned himself in a canal. This man evidently had delusions and insane suspicions, and his little foolish tricks are strongly indicative to my mind of failure of brain-power and possibly commencing dementia; that there was a strong element of melancholia beneath the surface of his disease appears evident to me from his committing suicide. Another of these moral lunatics is recorded as having the delusion that all the persons living in the house with him disliked him, and he confessed that he heard whispers of malevolence and abhorrence. This case was evidently one of the worst forms of insanity—the veritable insane demon who harbors delusions of persecution and hears irritating and deriding voices. To call such a man a moral lunatic without affection of his "intellect," is a use of terms which to me is worse than an error in definition—it is an injustice to humanity. Another case was a sober and industrious farmer, who became wild, excitable, full of schemes and absurd projects; bought cattle and stock for which he had no use, and a carriage which was much more elegant than he was accustomed to; he called on a man in the middle of the night to take him out to survey his farm. This man is reported to have recovered in an asylum, but my diagnosis of his case at this distance is *dementia paralytica* with an early remission, which deceived his physicians into the belief that he had recovered his lost conscience. This case I regard as an important pointer, for it suggests that many of these so-called moral lunatics are simply cases in the early stages of grave forms of insanity, who render themselves conspicuous by that erratic conduct and change of character which are early symptoms, and difficult often of interpretation. The whole texture of the brain is changed, and that specialized act which has been called ideation is perverted. The sensations received do not fall into a sound and active cerebral machine to be reflected again as conscious and intelligible acts, but the brain acts are perverted, weakened, and confused in all the relations and affairs of life. This suggests to me the difficulty often of following these abnormal brain-processes. There is no more difficult problem set before the physician than to unravel the complexities of the insane brain. Its suspicions are so varied and its associations so complex, that it seems sometimes as though it might require the prescience and insight of the greatest of poetic or philosophic minds. A patient whom I examined, and who afterward perished in the burning of the Blockley Insane Department, refused to eat because he had cursed the giver of food in his heart, but the connection of his conduct with a concealed delusion was for a long time not apparent. Another patient of the writer tore up her Catholic prayer-book, apparently in an unseemly rage of moral imbecility, but when questioned closely acknowledged the delusion that anyone who said the same prayers as she said would deprive her of a certain mysterious power which she possessed; and another patient, who had some extravagant religious delusions and a hyperæsthetic conscience, and who, nevertheless, without apparent reason slandered and abused her husband in the most heterodox manner, was at last brought to the confession of the astounding delusion that her husband had grown tired of his normal sexual relations with her, and intended to cut another hole in her abdomen in order that he might enjoy a change!

It is to be noted that moral insanity or imbecility is described especially in children, even more than in adults, and this is significant. In children cerebral activity is

[1] Pinel's treatise, p. 154.

more concerned about objects which immediately affect themselves, their comfort, amusements, and various gratifications. There is, in fact, much of the animal in them. They do not think or reason much about abstract and remote objects, relations and interests which claim the attention of the grown man, and about which the adult lunatic is apt to form his delusions. The child is pleased with a trifle, deeply interested in his animal appetites, and much harassed by discipline. The man is involved in the deadly struggle for existence, and is brought face to face with the anxious problems of fortune, friendship, religion, and destiny. To the deficient intellect of the imbecile child, bent upon self-indulgence, the greatest good and the readiest methods of self-assertion may seem to be obtainable by theft, incendiarism, and insubordination, while in the man the more complex delusions of persecution and religious melancholia fill up the measure of his woe, just as fidelity and worship widened the mental horizon of his perfect health. I speak now of those children who are real imbeciles, whose minds, if thoroughly tested, would show defective brain-power, and who are called moral idiots with good intellects because apparently their skulls are not as crooked as their conduct. I do not refer to the spurious cases who are occasionally reported, as, for instance, the kleptomaniac whose case is quoted by Bucknill and Tuke, who made bargains with the merchants that for a nominal sum of blackmail he would not steal from them. I do not call such a scamp by a Greek scientific word of five syllables, and I fear that his heaven-sent destiny is the county jail. Neither do I refer to such cases as these eminent authors describe in a patient who was a pyromaniac, and was such a bad girl that she resembled a serpent in her movements. "Her skin," we are told, "was also spotted like a common species of snake!" It is impossible for me to determine from this whether a spotted skin is a symptom of moral imbecility or whether it is a custom of serpents to set fire to houses, and in the double doubt I am willing to assign the tale to the other snake-stories of the newspapers.

Erotomania is not an insanity at all as described by many writers. Although increase and perversions of the sexual appetite are not uncommon in different forms of mental disease, I have seen several curious cases in which the trouble was entirely intellectual, rather than moral or sexual. A middle-aged buxom woman came one day, bewailing her uncontrollable lust, which she said she had endeavored to gratify with a number of men, although living an apparently happy and virtuous life with her husband. She was excitable and emotional as she talked, and easily became confused, almost incoherent, in her language. The longer she talked the greater the number of her paramours became, and the more exaggerated the details of her illicit relations grew. It was soon apparent that her self-accusations were delusions, and when questioned closely on the subject she broke down with the statement that her mind was so confused that she did not know whether she told the truth or not. I saw an old lady recently who was weeping constantly, and telling every person she met that she had committed adultery with a worthless fellow about town; but the good woman's age and appearance were enough to acquit her Lothario.

In the Annual Report of the Elmira State Reformatory, N. Y., for 1886, there is a most interesting account, by Dr. H. D. Wey, of an experimental class in physical culture. This class was composed of twelve inmates of the institution for the purpose of determining how far their cerebral condition could be improved by frequent baths, calisthenics, and physical culture. They seem to be as nearly moral imbeciles as could be well picked out, and in his admirable description Dr. Wey has taken the pains to give us an analysis of not only their "moral" but also their "intellectual" acquirements. Their ages were from nineteen to twenty-nine. The moral capital of these twelve men is summed up as follows: One was convicted for assault, five for burglary in the third degree, one for grand larceny in the first degree, three for grand larceny in the second degree, one for rape, and one for attempted rape. The doctor says truly that the offence of such men when against property is usually such as calls for no great amount of ingenuity, but when committed against the person is of an aggravated form and brutish in details, suggesting uncontrolled passion. This experimental class were serving an average sentence of seven and one-half years. Most of them had been intemperate. Not one had learned a trade. Their environment before their crimes was bad, many having had intemperate parents, and one an insane, and another an epileptic, mother. In physiognomy many in their photographs are typical of the crime class, and in two the receding forehead is almost typical of idiocy. The faces express mental hebetude and moral obliquity. The "intellectual" capital of these men is summed up as follows: The ignorance of some was so great that they were unable to tell in what country they lived. They were without purpose or ambition, and seemed simply to exist. "An idea of their mental attainments can be formed when it is said that one could neither read nor write; one barely do either; four understood the successive steps necessary to work an example in long division, but could never obtain the correct answer; while the balance were wrecked upon the shoals of rudimentary arithmetic from notation to simple division." It certainly cannot be said that the intellectual status of these men is any better than their moral status. Their whole cerebral activity is very bad.

The class of lunatics from whom are recruited most of the criminal insane comprises the patients with elaborate, systematized delusions. These are the monomaniacs, or, as the Germans call them, the cases of original insanity, or *Primäre Verrücktheit*. This has sometimes been called the "insanity of character." Its roots are deep in the very construction of the man's brain; he was born with a bad brain, which is bound not to perform properly its function of ideation. It will not elaborate good thought or sound sentiment in whatever environment it is placed and whatever sensations stimulate it to its special reflexes of comparison and action—at least thus we are taught to believe of these congenital fools. Just here is where a fallacy, I think, creeps into the admirable logic of those who have described this class. While it is true, in every sense, that there is a class of men born with poorly constructed brains, it is not so applicable a truth that they must necessarily be forever in the grip of a fate which holds them all equally irresponsible lunatics. Men are born with every grade of brain-power, from the microcephalic idiot to the sage whose cerebral masses weigh sixty ounces. Character is a varying quality, not always strictly in proportion to the amount and quality of a brain, but also in proportion to the character of the environments of that brain. If there is any truth in the doctrine of evolution, or any force in our systems of education, it seems to me to rest upon this truth. Otherwise we are all the most unfortunate fatalists, and, in a literal sense, the sins of our great-grandfathers are visited upon us without amendment or expiation possible on our parts. Hence this doctrine of original insanity, while attractive to the ear and eye, bears a fallacy with it if extended too far. Insanity is not a mere peculiarity of character, else this doctrine may extend its long arms until it embraces all the oddities and eccentricities and notions and fallacies and sins of mankind, or until one-half of the human race is caught by this *octopus* of the extreme school of alienists. Insanity must be conceded to be something more definite than this, especially criminal insanity, wherein arises the question of responsibility under the law. If Erskine's test of delusion is applicable at all, it is certainly to this class of lunatics, for insane delusion, fixed and logical, is the essence of their disease; it supplies the motive, usually, of their crimes (whether its connection with the crime can be traced or not); it dominates their lives and perverts all their conceptions of moral, social, and legal relations. Unless such a positive perversion of cerebral activity can

be shown it seems very doubtful if these "primary cranks" have passed from the borderland of folly and wickedness into the neighboring field of irresponsible lunacy. "No one," says an old legal writer, "is of perfectly sound mind but the Deity;" but while this may be conceded to the pessimist it can never be admitted as a scientific axiom in medical jurisprudence. We must have some secure ground to tread upon, and some certain landmarks when we come to pass judgment upon a man's mental health and his criminal responsibility, otherwise the decision may be no more admirable than that which declared General Beauregard insane after the first battle of Bull Run because he had lost the fight and yet was seen playing in an idle manner with a parrot in his tent; or the judgment which proclaimed Edmund Burke, the orator, to be an emotional lunatic because, when they brought him the favorite horse of his dead son, he threw his arm on the animal's neck and wept. The Philistines could see in this no more than the morbid sentimentalism of the author of "Tristram Shandy" when he wept over the agonies of a dying jackass!

The writer cannot but feel, in common with his profession, a prejudice against hard and fast dogmatic tests of insanity. It is in this respect that the physician has all along been apt to part company with the lawyer. This arises in part from the directly opposite positions taken by the two in regard to the case in issue. The physician, searching for disease, may be too apt sometimes to construe slight and irrelevant symptoms as indicative of what he seeks, while the lawyer, upon the bald assertion of the law that every man is in normal health until he is proved to the contrary, is always too prone to resist anything but the most glaring and unmistakable signs. It thus happens that the medical definition has sometimes been stretched so wide that it includes cases which shock the common-sense of the most intelligent, while the legal tests have been made so narrow and unscientific that it is difficult to include in them some of the most patent cases of insanity. The test of "delusion" is, I believe, in some forms of insanity an applicable one, but it certainly will not include all classes of mental disease, while the test of knowledge of "right and wrong" is founded, I think, upon a misconception of the unity of the brain-function not unlike that which has supplied the doctrine of moral insanity. A scientific diagnosis ought to be made in court just as in a hospital. I believe that the conception, and rigid adherence to the conception, of the cerebrum as an individual unit, whose special act is always a reflex process of ideation, tends to a satisfactory definition and classification of insanity, as well as to an intelligible application of our knowledge to the solution of medico-legal questions, much superior to anything attainable by the distinctions of the metaphysicians or the arbitrary tests of the judges. This process of ideation may be depressed or exalted (as in melancholia or mania), it may be perverted (as in monomania), it may be confused and incoherent (as in a variety of forms), or it may be utterly disorganized (as in dementia), but I certainly have not yet seen a case of insanity in which it was not in one or the other of these states.

Southwest Corner Walnut and Fortieth Streets,
Philadelphia, Pa.

Iodol in Diphtheria.—In order to test the statements of Dr. Mazzoni, Dr. L. L. Stembo, of Vilna, tried (*Proceedings of the Vilna Medical Society*, No. V., 1887, p. 114) the local use of iodol in seven cases of diphtheria, two of which were severe. The drug was applied either alone, in powder, or in the form of a solution (℞. Iodoli, ʒss; liq. vini, ʒss; glycerini, ʒiijss.). All the patients recovered after treatment lasting from four to six days. The advantages claimed by Dr. Stembo for iodol are its complete harmlessness, its freedom from unpleasant smell or taste, the painlessness of its application, and the absence of any untoward secondary effects, such as loss of appetite, nausea, vomiting, etc.

CONTRIBUTION TO THE STUDY OF CEREBRO-SPINAL FEVER.[1]

By J. LEWIS SMITH, M.D.,

Clinical Professor of Diseases of Children, Bellevue Hospital Medical College.

Cerebro-spinal fever was probably unknown prior to the present century. It was recognized and described in Europe in 1802, and since then numerous epidemics of it have occurred in isolated localities in both continents. It was in the first half of this century regarded as a painful and dangerous epidemic malady, attacking chiefly the young, occurring suddenly and unexpectedly in places widely separated, among people engaged in diverse occupations, and living under different conditions as regards soil, climate, and food. After some weeks or months it suddenly or gradually, but completely, disappeared, so that no more cases occurred for a series of years; but since 1860 it has appeared in this country in another phase. It is becoming established, or, to use the phrase commonly employed in medical literature, naturalized in the cities of the United States. For some years not a week has passed, or but few weeks have passed, without the report of deaths from this disease in New York, Philadelphia, Jersey City, and Chicago—Chicago being the city in which it has caused the largest number of deaths in proportion to the population. During last year it occurred in Cincinnati, Minneapolis, Denver, Norfolk, Boston, Worcester, New Haven, Albany, Syracuse, Auburn, Milwaukee, Wilmington, Detroit, Baltimore, Charleston, Toledo, Mobile, Salt Lake, Grand Rapids, Providence, Chattanooga, Hartford, New Orleans, Fall River, Richmond, Knoxville, and Nashville. It is probably already permanently established in Cincinnati, St. Louis, Minneapolis, Newark, and San Francisco, since deaths from it have been reported in these cities during many consecutive weeks. It appears to be extending most rapidly, and causing the largest number of deaths in the cities along the line of western travel from New York. Whatever may be the explanation, it is extending much more rapidly in the Northern than in the Southern cities, or the cities in the late slave States. In the Southern cities usually not more than one death is reported during the week, and only in a very few weeks during the year.

In New York City, prior to 1866, only four deaths were announced from what might have been cerebro-spinal fever, since in 1838 two deaths were reported from so-called spotted fever, one in 1850, and one in 1861. What was the nature of this spotted fever is now a matter of conjecture. In 1866, 18 patients died of cerebro-spinal fever within the city limits, and not a year has passed since without deaths from it, and in the last few years not a week. From 1866 to 1872 the annual deaths from this disease varied from 18 to 48. Commencing in December 1871, and continuing during the first half of 1872, a severe epidemic occurred, producing a large mortality, destroying the eyes of some, and leaving permanently deaf many who otherwise fully recovered. In this epidemic the physicians of New York were fully aroused to the importance of the disease which was causing so much suffering, and which attacked the lower animals, especially the jaded horses of the city car and stage lines, not a few of them dropping down in harness, so suddenly did the attacks occur. In 1872, 782 deaths occurred from it within the city limits, chiefly of children. This epidemic appeared to produce a greater dissemination of the disease, and more firmly establish it in the city; for since then the annual deaths from it have varied between 97 in 1878 and 461 in 1881. In Philadelphia cerebro-spinal fever began in 1863, causing 49 deaths in that year, and it has never been absent from that city since. Professor Stillé states that between 1863 and 1882 it caused 2,049 deaths within the city limits. In Philadel

[1] Abstract of a paper read before the Northwestern Medical and Surgical Society of New York, March 16, 1887.

phia, as in New York, it has for some years produced a nearly uniform weekly mortality.

The etiology of cerebro-spinal fever is a matter of great interest. That it is produced by a micro-organism is generally admitted. Doctor A. Fränkel, as well as other European microscopists, have made a study of the bacteria found in the blood and tissues of those affected with it. At the meeting of the Berlin Medical Society, held February 12, 1883, Herr Leyden showed, under the microscope, specimens of micrococci found in a case of cerebro-spinal fever.[1] They had an oval shape, were mostly in pairs, and were faintly tremulous. They resembled those found in pneumonia and erysipelas; but Leyden did not think them identical. At the same meeting Herr Baginsky related cases which seemed to show that in some instances the exciting cause of cerebro-spinal fever and pneumonia might be identical.

Dr. V. O. Pushkareff,[2] connected with one of the barrack infirmaries in St. Petersburg, states that in five cases of croupous pneumonia, in which cerebro-spinal meningitis occurred as a complication, he discovered in the pus taken from the cerebral meninges swarms of micrococci, whose appearance under the microscope seemed identical with that of Friedländer's pneumococcus. They were either isolated or in groups of two, seldom in four, having distinct capsules, and they were absent from the fluid taken from the meninges in simple pneumonia. He was able to cultivate the micrococcus taken from the meningeal pus, and the cultivated microbes, like their parents, presented an appearance identical with that of the pneumococcus. Moreover, Eberth, in a case of meningitis following pneumonia, believes that he found the same micrococci in the lungs and in the liquid exuded from the inflamed pia mater; Fränkel[3] also states that he obtained from the purulent exudation in the pia mater in a case of meningitis, occurring with pneumonia, a microbe resembling that in the pneumonic exudation. From the investigations of so many competent microscopists, therefore, it appears that the microbe found in the exudate of the meninges in cerebro-spinal fever, and which is supposed to sustain a causative relation to this disease, bears a close resemblance in form to the pneumococcus, if it be not identical with it. But we would infer, from the fact that croupous pneumonia is such a universal disease, occurring in localities where there is no cerebro-spinal fever, that the causes of the two must be different; or if there be a form of croupous pneumonia which is produced by the same microbe as that of cerebro-spinal fever, the pneumonia which is of universal occurrence may have a different origin. The microbic causation of cerebro-spinal fever needs further investigation, which it will doubtless receive, before positive statements can be made.

Physicians have studied cerebro-spinal fever as an idiopathic or primary malady; but its occurrence as a complication of other diseases has not received the attention which it requires. Fagge, in his recently published "Practice of Medicine," calls attention to this fact, and especially to its occurrence as a complication of croupous pneumonia, fifteen cases of which occurred in Erlangen, and he alludes to its complicating pleurisy, tonsillitis, and scarlatinal nephritis. I have seen it occur as a complication of typhoid fever, in which there could be no doubt as to the diagnosis of the primary disease, and also as a complication of the intestinal catarrh of infancy.

It is evident, from the nature of cerebro-spinal fever, that wherever it occurs the full number of cases is not reported. Some cases terminate so quickly in convulsions and death that a clear diagnosis is not made. I might cite a recent case of this kind, occurring in one of the institutions, in which the diagnosis was not made until the autopsy disclosed the nature of the malady. Those who have seen much of cerebro-spinal fever and are familiar with its symptoms will, I think, often recognize this disease in cases which are reported in the journals under other names; such as *infantile cerebral paralysis*, *hemiplegia cerebralis spastica* of Heine, or Strümpell's *poliencephalitis acuta*. In a recent number of THE MEDICAL RECORD the case of a child of four and a half years is detailed, who was suddenly seized with eclampsia and high fever, followed by loss of speech and right hemiplegia. The case is reported under the heading "Infantile Cerebral Paralysis," but the symptoms so closely resembled those of certain cases of cerebro-spinal fever that there can be little doubt in my mind that this was the disease. Paralysis or aphasia, suddenly occurring, is not unusual at an early stage of cerebro-spinal fever. Thus a boy of ten years, treated for cerebro-spinal fever in 1878, was unable to move his legs one hour after the commencement of the attack, and in 1882 I attended a girl of three years, with the same disease, who lost her speech on the second day of the fever and did not recover it until the lapse of two and a half months. These remarks are made to show that probably the published statistics of cerebro-spinal fever only give approximately the number of cases. Perhaps, also, the mistake is sometimes made in the opposite direction, and what are cases of some other form of meningeal or cerebral disease are regarded as cerebro-spinal fever.

Many monographs have been published on cerebro-spinal fever, as it occurs in the epidemic form, and but little attention has been bestowed on the symptoms or character which it presents, or the changes which it undergoes when it occurs as an endemic or naturalized disease. The material of many of the papers has been obtained by observing epidemics and studying cases in rural localities. The naturalized disease must, of course, be observed in the cities, for there is no rural locality, so far as I am aware, in which cerebro-spinal fever is permanently established. In New York the naturalized disease differs in some respects from the form exhibited in the epidemic of 1872, and in other epidemics throughout the country. The naturalized disease appears to be accompanied by a less profound blood-change. Although every year seeing a considerable number of cases, I have not in the last ten years seen one with the livid spots upon the surface, due to subcutaneous extravasation of blood, which were so common in the epidemic of 1872, and which have been common in epidemics both in this country and in Europe, so that they have given the name "spotted fever" to the malady.

It is well known that in the epidemic form of cerebro-spinal fever the attack is abrupt and with little or no premonition. The exact moment of its commencement can be stated, but in some instances in the naturalized disease the attacks seem to me to come on more gradually, so that a day or more may elapse before we are certain that the sickness involves seriously the cerebro-spinal axis.

Some writers have expressed the opinion that the time in the year or the season influences the occurrence of epidemics of this malady; but the frequency of the naturalized disease seems to be pretty uniform in the different seasons and months. Thus, in this city, the reported deaths from cerebro-spinal fever in 1883 were as follows:

January	20	July	20
February	24	August	13
March	24	September	17
April	18	October	15
May	30	November	10
June	19	December	13

The bulletins of the Health Board for 1886, which I have been able to obtain covering thirty-three weeks, show that in every week the number of deaths from cerebro-spinal fever has been nearly the same, varying from two to six or eight. In the spring, summer, autumn, and winter months the rate of deaths was nearly uniform.

[1] Deutsche Med. Wochenschrift, April 4, 1883.
[2] Ejenedelnaia Klin. Gazeta, April 21, 1885.
[3] Deutsche Med. Wochenschrift, November 13, 1886.

My observations lead me to think that the younger the child the more frequently is cerebro-spinal fever overlooked, and some other disease diagnosticated. Nevertheless, the statistics of this city show that there is a larger number of fatal cases under the age of one year than in any other year, and the number of deaths gradually diminishes as the age increases. Thus, in 1883 the ages of those who died from this disease were as follows:

Under one year	57	Twenty to twenty-five years	7
One to two years	31	Twenty-five to thirty years	3
Two to three years	22	Thirty to thirty-five years	4
Three to four years	12	Thirty-five to forty years	3
Four to five years	9	Forty to forty-five years	1
Five to ten years	37	Forty-five to fifty years	2
Ten to fifteen years	18	Fifty to sixty years	1
Fifteen to twenty years	15	Over sixty years	1

The weekly bulletins of thirty-one weeks in 1886 give the ages of fatal cases of cerebro-spinal fever as follows:

Under one year	28	Fifteen to twenty years	7
One to two years	20	Twenty to thirty years	10
Two to three years	18	Thirty to forty years	4
Three to four years	7	Forty to fifty years	3
Four to five years	6	Fifty to sixty years	2
Five to ten years	16	Sixty to seventy years	4
Ten to fifteen years	6		

Not a few cases occur, in this city, in infants of the age of three or four months. An infant of four months died of cerebro-spinal fever in the New York Infant Asylum, the nature of the disease not being known until it was revealed by the autopsy.

Another interesting fact in reference to this disease, as it occurs in New York City, is that, although the city has a wide area, it occurs in every part of it. Thus the death-statistics in 1883 show that deaths occurred from cerebro-spinal fever in every ward except the First—the largest number, to wit, 39, being in the Nineteenth Ward, and the next largest, 20, being in the Seventh Ward. The death-statistics of thirty-three weeks of 1886—the statistics of the remaining nineteen weeks not being in my possession—show that deaths occurred from cerebro-spinal fever in all the wards except the Second, Third, and Twenty-fourth—the largest number, 24, being also in the Nineteenth Ward, and the next largest, 15, being in the Seventh Ward. Therefore cerebro-spinal fever has extended over the entire city, and, so far as we now see, is as firmly established as is diphtheria. These two scourges, admitted into this great and growing metropolis during the professional life of physicians now in active practice, are, from present appearances, likely to increase rather than diminish, notwithstanding sanitary regulations. We must submit to the inevitable fact that as they have desolated many families, producing an immense amount of suffering and blighting the hopes of parents in the present generation, so they will continue in full activity and probably increasing prevalence in the future, unless those who succeed us discover some more effectual way of preventing their occurrence.

The statistics, therefore, of this city show a wide diffusion of the specific principle of cerebro-spinal fever. If this disease have, as is believed, a microbic origin, the microbe has extended over the length and breadth of New York, and it has found conditions equally favorable for its development and extension in Jersey City, where for many months it has been as prevalent and severe as in this city. It is a remarkable fact, in reference to cerebro spinal fever, many times appearing in its history, that of two adjacent localities having apparently the same conditions as regards soil and climate, and with the same diet and occupations of the inhabitants, one is scourged by it while the other nearly or quite escapes. While New York has suffered so severely, Brooklyn has thus far nearly escaped. In the latter great city, with its population of 600,000, I find that in 1883 only two deaths from cerebro-spinal fever were announced. The wide diffusion of the specific principle of cerebro-spinal fever over New York island, adjacent portions of Westchester County, and across the river in Hudson County, New Jersey, in which county are Jersey City and Hoboken, contrasts with marsh miasm, which is indigenous in portions of the same localities, but has always been confined to limited areas.

Such are some of the more conspicuous facts relating to the establishment of cerebro-spinal fever in New York, and what is occurring in this city is probably also taking place in the other American cities where this malady has become naturalized. In some of these cities, as Chicago, the death-rate from cerebro-spinal fever is larger than in New York. Are the European cities undergoing similar experiences?[1] Professor E. Henoch, of Berlin,[2] describes a non-tubercular meningitis occurring among children, which he states is more frequent than is commonly believed. It is a protracted disease, attended by alternate aggravation and abatement of symptoms. It generally begins abruptly, with active fever, intense headache, frequent vomiting, and is attended by rigidity of the nucha, cutaneous hyperæsthesia, and sometimes contraction of the muscles of the extremities. After many weeks, during which the mind of the physician alternates between hope and despair, a majority of the patients, seen by Professor Henoch, gradually recovered. The writer adds that the true nature of this meningitis is unknown. Berlin, if I am not mistaken, was visited by an epidemic of cerebro-spinal meningitis in the spring of 1885, and I would ask the distinguished professor, whom we all honor for his contributions to pædiatric literature, if he is not now seeing and treating the naturalized disease.

Clinical Department.

A CASE OF COMPOUND COMMINUTED FRACTURE OF THE SKULL, AND EXTENSIVE CEREBRAL LESIONS WITHOUT CEREBRAL SYMPTOMS.

Dr. James S. Carpenter, of Pottsville, Pa., reports the following case: "John M——, a brakeman, about thirty-eight years of age, while coupling cars, had his head caught between the bumper of one of them and a heavy log of wood that had been jolted forward from the next car. He received several large lacerated wounds of the scalp, and a compound comminuted depressed fracture of the skull in the left parietal, temporal, and orbital regions. He walked quite a distance before falling, though bleeding profusely from his wounds. After being temporarily cared for, he was sent to his home, a distance of thirty-five miles, where he was operated upon by Dr. John T. Carpenter, assisted by Dr. D. W. Bland and the writer. The patient was comatose, with stertorous breathing, pupils contracted and insensible to light, and so restless that considerable restraint was necessary to keep him in bed. The pulse was 60, and the temperature subnormal. At first glance it seemed as though the whole of the left side of the skull, at a level with the ear, had been carried away. The scalp was extensively lacerated, and through the several openings cerebral matter was constantly oozing, while there was a depression, extending from the middle of the left supraorbital ridge to a point about midway between the anterior and posterior regions of the skull, into which the hand could easily be laid. The fragment of the left frontal bone had been driven downward and backward, and was partially rotated, so that its anterior surface alone was visible. It required considerable force to effect the removal of this fragment, as it had been driven into, and was very firmly held by, the body of the sphenoid. The second piece removed was a part of the sphenoidal wing. Like the first fragment, this was imbedded deeply in the brain mass, and after its removal, one could distinguish, with the index-finger,

[1] Schmidt's Jahrb., No. 8, 1886.
[2] Zur Pathologie der Meningitis cerebro-spinalis.

the body of the sphenoid and could make out the clinoid processes. The third and last fragment removed was a portion of the parietal bone. This had been driven so far into the brain as to escape detection, until the writer, wishing to determine for himself the extent of the brain injury, discovered it just over the petrous portion of the temporal bone. The driving in of this fragment had, of course, injured the meningeal artery, and on its removal quite a severe hemorrhage occurred, which was controlled by packing lint down into the wound close to the bone. The patient bore the operation well, and was still under the influence of the chloroform when it was completed. Carbolized dressings were applied over the wound, and an ice-bag was kept to the head. Consciousness was fully restored by the operation, and the patient was able to get up to urinate, and put on, almost unaided, a clean shirt. In fact, so fully convinced was the patient that he would recover that he wished to discharge his physician from any further attendance. During the three following days the patient's mental condition was good, the vision was unimpaired, and the temperature was normal. On the fourth day after the operation the temperature rose to 102.5°, there was some pain in the head, and the patient was restless. The next day there was muttering delirium, followed by coma, and death occurred five days after the operation.

"No post-mortem examination could be obtained. Most of the injury caused by the accident was dealt to that part of the brain whose surface boundaries may be defined as the fissure of Rolando and that of Sylvius, in which area are located many important centres, the destruction of which should have given rise to certain well-defined symptoms, but which the history of the patient does not show to have existed. At no time after the removal until the day before the patient's death was there noted any paralysis, either facial or of the extremities, nor was aphasia present. Indeed, so marked was the improvement in the patient's condition, and so complete was the absence of unfavorable symptoms, that it was a difficult matter to persuade the family of the unfortunate man that recovery was impossible."

POISONING FROM EGGS.
